EDITORS

First Edition

Lewis R. Goldfrank, MD, Robert Kirstein, MD

Second Edition

Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD, Neal A. Lewin, MD, Richard S. Weisman, PharmD

Third Edition

Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD, Neal A. Lewin, MD, Richard S. Weisman, PharmD, Mary Ann Howland, PharmD, Alan G. Kulberg, MD

Fourth Edition

Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD, Neal A. Lewin, MD, Richard S. Weisman, PharmD, Mary Ann Howland, PharmD

Fifth Edition

Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD, Neal A. Lewin, MD, Richard S. Weisman, PharmD, Mary Ann Howland, PharmD, Robert S. Hoffman, MD

Sixth Edition

Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD, Neal A. Lewin, MD, Richard S. Weisman, PharmD, Mary Ann Howland, PharmD, Robert S. Hoffman, MD

Seventh Edition

Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD, Neal A. Lewin, MD, Mary Ann Howland, PharmD, Robert S. Hoffman, MD, Lewis S. Nelson, MD

Eighth Edition

Neal E. Flomenbaum, MD, Lewis R. Goldfrank, MD, Robert S. Hoffman, MD, Mary Ann Howland, PharmD, Neal A. Lewin, MD, Lewis S. Nelson, MD

Ninth Edition

Lewis S. Nelson, MD, Neal A. Lewin, MD, Mary Ann Howland, PharmD, Robert S. Hoffman, MD, Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD

GOLDFRANK'S TOXICOLOGIC EMERGENCIES TENTH EDITION

**ROBERT S. HOFFMAN, MD, FAACT,
FACMT, FRCP Edin, FEAPCCT**

Professor of Emergency Medicine and Medicine
Director, Division of Medical Toxicology
New York University School of Medicine
Attending Physician, Emergency Medicine
Bellevue Hospital Center and New York University
Langone Medical Center
Consultant, New York City Poison Center
New York, New York

**MARY ANN HOWLAND, PharmD,
DABAT, FAACT**

Clinical Professor of Pharmacy
St. John's University College of Pharmacy and
Health Sciences
Adjunct Professor of Emergency Medicine
New York University School of Medicine
Bellevue Hospital Center and New York University
Langone Medical Center
Senior Consultant in Residence
New York City Poison Center
New York, New York

**NEAL A. LEWIN, MD, FACEP, FACMT,
FACP**

Druckemiller Professor of Emergency Medicine
and Professor of Medicine (Pharmacology)
New York University School of Medicine
Director, Didactic Education
Emergency Medicine Residency
Attending Physician, Emergency Medicine and
Internal Medicine
Bellevue Hospital Center and New York
University Langone Medical Center
Consultant, New York City Poison Center
New York, New York

**LEWIS S. NELSON, MD, FAACT, FACEP,
FACMT**

Professor of Emergency Medicine
Vice-Chair for Academic Affairs
Department of Emergency Medicine
New York University School of Medicine
Attending Physician, Emergency Medicine
Bellevue Hospital Center and New York University
Langone Medical Center
Director, Fellowship in Medical Toxicology
New York City Poison Center and New York
University School of Medicine
New York, New York

**LEWIS R. GOLDFRANK, MD, FAAEM,
FAACT, FACEP, FACMT, FACP**

Herbert W. Adams Professor and Chair
Department of Emergency Medicine
New York University School of Medicine
Director, Emergency Medicine
Bellevue Hospital Center and New York
University Langone Medical Center
Medical Director, New York City Poison Center
New York, New York

Editor Emeritus

**NEAL E. FLOMENBAUM, MD,
FACP, FACEP**

Professor of Clinical Medicine
Weill Cornell Medical College of Cornell
University
Emergency Physician-in-Chief
New York-Presbyterian Hospital
Weill Cornell Medical Center
Consultant, New York City Poison Center
New York, New York

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

TERMS OF USE

This is a copyrighted work and McGraw-Hill Education and its licensors reserve all rights in and to the work. Use of this work is subject to these terms. Except as permitted under the Copyright Act of 1976 and the right to store and retrieve one copy of the work, you may not decompile, disassemble, reverse engineer, reproduce, modify, create derivative works based upon, transmit, distribute, disseminate, sell, publish or sublicense the work or any part of it without McGraw-Hill Education's prior consent. You may use the work for your own noncommercial and personal use; any other use of the work is strictly prohibited. Your right to use the work may be terminated if you fail to comply with these terms.

THE WORK IS PROVIDED "AS IS." MCGRAW-HILL EDUCATION AND ITS LICENSORS MAKE NO GUARANTEES OR WARRANTIES AS TO THE ACCURACY, ADEQUACY OR COMPLETENESS OF OR RESULTS TO BE OBTAINED FROM USING THE WORK, INCLUDING ANY INFORMATION THAT CAN BE ACCESSED THROUGH THE WORK VIA HYPERLINK OR OTHERWISE, AND EXPRESSLY DISCLAIM ANY WARRANTY, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO IMPLIED WARRANTIES OF MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE. McGraw-Hill Education and its licensors do not warrant or guarantee that the functions contained in the work will meet your requirements or that its operation will be uninterrupted or error free. Neither McGraw-Hill Education nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill Education has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill Education and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

Neal E. Flomenbaum, MD, FACP, FACEP Editor Emeritus

With the publication of the ninth edition of Goldfrank's Toxicologic Emergencies, Neal Flomenbaum informed us of his decision to step down as an editor in order to be able to devote more time to his growing interests in geriatric emergency medicine and prehospital care, while continuing to fulfill his clinical and administrative responsibilities as Chief of Emergency Medicine at New York Presbyterian Hospital-Weill Cornell Medical Center and as Medical Director of its extensive prehospital care system.

In 1979, Dr. Flomenbaum accepted an offer from Lewis Goldfrank to join him at New York University Bellevue Hospital as Associate Director of Emergency Services and Consultant (later, Chief Consultant) to the New York City Poison Control Center, and their subsequent collaborations resulted in many of the outstanding features of this textbook. Frequently, ideas and concepts Neal and Lewis developed for presenting clinical toxicology were recognized for their value to the textbook and then developed further by both, with considerable input and efforts by Neal Lewin, Richard Weisman, Mary Ann Howland, Robert Hoffman, and Lewis Nelson. Thus, an idea for a 1984 review article entitled “Newer Antidotes and Controversies in Antidotal Therapy,” written to familiarize clinicians with the appropriate use of antidotes in patient management, became “Antidotes in Depth,” a signature feature of this book.

Similarly, the idea for an organ system track in the NYU postgraduate toxicology courses that Neal and Lewis codirected in the early 1980s became “The Pathophysiologic Basis of Medical Toxicology: The Organ System Approach” in the textbook. This section, in turn, suggested another section entitled “The Biochemical and Molecular Basis of Medical Toxicology.”

Additional ideas followed for making Goldfrank's Toxicologic Emergencies more accessible both as a teaching and a reference resource. A monthly case-based consultants' meeting at the New York City Poison Control Center was modeled after the successful format originated in the first edition of this book, and many of the cases discussed there were adapted for the text and related review books. Placing essential reference tables on the inside front and back covers of the textbook proved to be another useful feature, and Neal is particularly proud of the unique way the textbook acknowledges previous authors at the end of chapters. In addition to his ideas and his organizational and editorial contributions, Neal has written, coauthored, or contributed to dozens of chapters since 1982, including those on salicylates, rodenticides, and managing the acutely poisoned or overdosed patient.

Neal Flomenbaum first became interested in medical toxicology because of the clinical challenges it presented to emergency physicians, internists, and pediatricians, and he has remained focused on these clinical aspects. His creative energies, talents, and contributions to the second through ninth editions of this book have helped transform a case-based introduction to clinical toxicology into the 2000 page textbook it is today, and these contributions will remain an important part of future editions.

Erythroxylum coca, the source of cocaine, is renowned in toxicology and medicine for its ritual use by ancient cultures, traditional use by modern indigenous peoples, role as the first pharmaceutical local anesthetic, and notorious use as an illicit drug of abuse. The molecule benzoylmethylecgonine (cocaine) highlights the complex structure of a plant alkaloid. At the cellular level, cocaine is a remarkable drug that blocks the reuptake of neurotransmitters (dopamine, norepinephrine, epinephrine, and serotonin), blocks neuronal and cardiac sodium channels, and causes vasoconstriction. The cardiotoxic effects are demonstrated on the electrocardiogram, which shows a classic ST segment anterior wall myocardial infarction in a young person who recently used cocaine. Although a true antidote to cocaine toxicity has yet to be developed, the vial represents the benzodiazepines, which have become the mainstay of therapy for psychomotor agitation that results from typical cocaine overdose.

DEDICATION

To the staffs of our hospitals, emergency departments, intensive care units, and outpatient venues, who have worked with remarkable courage, concern, compassion, and understanding in treating the patients discussed in this text and many thousands more like them

To the staff of the New York City Poison Center, who have quietly and conscientiously integrated their skills with ours to serve these patients and prevent many patients from ever needing a hospital visit

To all the faculty, fellows, residents, and students who have studied toxicology with us, whose inquisitiveness has helped us continually strive to understand complex and evolving problems and develop methods to teach them to others

To my wife Ali; my children Casey and Jesse; my parents; and my friends, family, and colleagues for their never-ending patience and forgiveness for the time I have spent away from them (R.H.)

To my husband Bob; to my children Robert, and Marcy and Doug; to my mother and to the loving memory of my father; and to family, friends, colleagues, and students for all their help and continuing inspiration (M.A.H.)

To my wife Gail Miller, my sons Dr. Jesse Miller Lewin, Dr. Justin Miller Lewin, and Dr. Alana Amarosa Lewin, and in memory of my parents. To all my patients, students, residents, fellows, and colleagues who constantly stimulate my being a perpetual student (N.L.)

To my wife Laura for her unwavering support; to my children Daniel, Adina, and Benjamin for their fresh perspective, youthful insight, and boundless energy; to my parents Myrna of blessed memory and Dr. Irwin Nelson for the foundation they provided; and to my family, friends, and colleagues who keep me focused on what is important in life (L.N.)

To my children Rebecca and Ryan, Jennifer, Andrew and Joan, Michelle and James; to my grandchildren Benjamin, Adam, Sarah, Kay, Samantha, Herbert, and Jonah who have kept me acutely aware of the ready availability of possible poisons; and to my wife, partner, and best friend Susan whose support was essential and whose contributions will be found throughout the text (L.G.)

ANTIDOTES IN DEPTH

Editor: Mary Ann Howland

Associate Editor: Silas W. Smith

Readers of previous editions of Goldfrank's Toxicologic Emergencies are undoubtedly aware that the editors have always felt that an emphasis on general management of patients who are poisoned or overdosed coupled with sound medical management is as important as the selection and use of a specific antidote in the vast majority of cases. Nevertheless, there are some instances when nothing other than the timely use of a specific antidote is an essential lifesaving intervention. For this reason, and also because the use of such strategies may be problematic, controversial, or unfamiliar to the practitioner as new therapeutic approaches continue to emerge and old standards are reevaluated, we have included a section (or sections) at the end of each chapter where an in-depth discussion of such material is relevant.

TABLE OF ANTIDOTES IN DEPTH

ACTIVATED CHARCOAL

Silas W. Smith and Mary Ann Howland

ANTIVENOM: SCORPION

Michael A. Darracq and Richard F. Clark

ANTIVENOM: SNAKES (NATIVE [US] VENOMOUS [CROTALINE AND ELAPID])

Anthony F. Pizon and Anne-Michelle Ruha

ANTIVENOM: SPIDER

Michael A. Darracq and Richard F. Clark

ATROPINE

Mary Ann Howland

BENZODIAZEPINES

Robert S. Hoffman, Lewis S. Nelson, and Mary Ann Howland

BOTULINUM ANTITOXIN

Silas W. Smith and Howard L. Geyer

CALCIUM

Mary Ann Howland

L-CARNITINE

Mary Ann Howland

DANTROLENE SODIUM

Kenneth M. Sutin

DEFEROXAMINE

Mary Ann Howland

DIGOXIN-SPECIFIC ANTIBODY FRAGMENTS

Mary Ann Howland

DEXTROSE (D-Glucose)

Larissa I. Velez and Kathleen A. Delaney

DIMERCAPROL (BRITISH ANTI-LEWISITE OR BAL)

Mary Ann Howland

EDETATE CALCIUM DISODIUM (CaNa₂EDTA)

Mary Ann Howland

ETHANOL

Mary Ann Howland

FLUMAZENIL

Mary Ann Howland

FOLATES: LEUCOVORIN (FOLINIC ACID) AND FOLIC ACID⁶⁹³

Mary Ann Howland

FOMEPIZOLE

Mary Ann Howland

GLUCAGON

Mary Ann Howland

GLUCARPIDASE (CARBOXYPEPTIDASE G₂)

Silas W. Smith

HIGH-DOSE INSULIN EUGLYCEMIA

Samuel J. Stellpflug and William Kerns, II

HYDROXOCOBALAMIN

Mary Ann Howland

HYPERBARIC OXYGEN

Stephen R. Thom

INTRAVENOUS FAT EMULSION

Theodore C. Bania

METHYLENE BLUE

Mary Ann Howland

N-ACETYLCYSTEINE

Robert G. Hendrickson and Mary Ann Howland

OCTREOTIDE

Mary Ann Howland and Silas W. Smith

OPIOID ANTAGONISTS

Lewis S. Nelson and Mary Ann Howland

PENTETIC ACID OR PENTETATE (ZINC OR CALCIUM) TRISODIUM (DTPA)

Joseph G. Rella

PHYSOSTIGMINE SALICYLATE

Mary Ann Howland

POTASSIUM IODIDE

Joseph G. Rella

PRALIDOXIME

Mary Ann Howland

PROTAMINE

Mary Ann Howland

PRUSSIAN BLUE

Robert S. Hoffman

PYRIDOXINE

Mary Ann Howland

SILIBININ

Mary Ann Howland

SODIUM AND AMYL NITRITE

Mary Ann Howland

SODIUM BICARBONATE

Paul M. Wax

SODIUM THIOSULFATE

Mary Ann Howland

SUCCIMER (2,3-DIMERCAPTOSUCCINIC ACID)

Mary Ann Howland

THIAMINE HYDROCHLORIDE

Robert S. Hoffman

VITAMIN K₁

Mary Ann Howland

WHOLE-BOWEL IRRIGATION AND OTHER INTESTINAL EVACUANTS

Silas W. Smith and Mary Ann Howland

CONTENTS

10TH EDITION

Contributors

Preface

Acknowledgments

1. Historical Principles and Perspectives

Paul M. Wax

2. Toxicologic Misfortunes and Catastrophes in History

Paul M. Wax

PART A

THE GENERAL APPROACH TO MEDICAL TOXICOLOGY

3. Initial Evaluation of the Patient: Vital Signs and Toxic Syndromes

Robert S. Hoffman, Mary Ann Howland, Neal A. Lewin, Lewis S. Nelson, and Lewis R. Goldfrank

4. Principles of Managing the Acutely Poisoned or Overdosed Patient

Robert S. Hoffman, Mary Ann Howland, Neal A. Lewin, Lewis S. Nelson, and Lewis R. Goldfrank

5. Diagnostic Imaging

David T. Schwartz

6. Laboratory Principles

Petrie M. Rainey

7. Medicolegal Interpretive Toxicology

Robert A. Middleberg

8. Techniques Used to Prevent Gastrointestinal Absorption

Lotte C. G. Hoegberg and Anne-Bolette Gude

A1. ACTIVATED CHARCOAL

Silas W. Smith and Mary Ann Howland

A2. WHOLE-BOWEL IRRIGATION AND OTHER INTESTINAL EVACUANTS

Silas W. Smith and Mary Ann Howland

9. Pharmacokinetic and Toxicokinetic Principles

Mary Ann Howland

10. Principles and Techniques Applied to Enhance Elimination

David S. Goldfarb and Marc Ghannoum

11. Use of the Intensive Care Unit

Kyle B. Enfield and Mark A. Kirk

PART B

THE FUNDAMENTAL PRINCIPLES OF MEDICAL TOXICOLOGY

SECTION I

BIOCHEMICAL AND MOLECULAR BASIS

12. Chemical Principles

Stephen J. Traub and Lewis S. Nelson

13. Biochemical and Metabolic Principles

Kurt C. Kleinschmidt and Kathleen A. Delaney

Appendix: Cytochrome P450 Substrates, Inhibitors, and Inducers

14. Neurotransmitters and Neuromodulators

Steven C. Curry, Ayrn D. O'Connor, Kimberlie A. Graeme, Kirk C. Mills, and Aaron B. Skolnik

15. Withdrawal Principles

Richard J. Hamilton

SECTION II

PATHOPHYSIOLOGIC BASIS: ORGAN SYSTEMS

16. Electrophysiologic and Electrocardiographic Principles

Cathleen Clancy

17. Cardiology Principles II: Hemodynamics

Robert A. Hessler

18. Dermatologic Principles

Jesse M. Lewin, Neal A. Lewin, and Lewis S. Nelson

C1. TRANSDERMAL TOXICOLOGY

Lewis S. Nelson

19. Fluid, Electrolyte, and Acid–Base Principles

Alan N. Charney and Robert S. Hoffman

20. Gastrointestinal Principles

Matthew D. Zuckerman and Richard J. Church

21. Genitourinary Principles

Jason Chu

22. Hematologic Principles

Marco L.A. Sivilotti

23. Hepatic Principles

Kathleen A. Delaney

24. Neurologic Principles

Rama B. Rao

25. Ophthalmic Principles

Adhi Sharma

26. Otolaryngologic Principles

William K. Chiang

27. Psychiatric Principles

Erin A. Zerbo and Andrea M. Kondracke

28. Renal Principles

Marc Ghannoum and David S. Goldfarb

29. Respiratory Principles

Andrew Stolbach and Robert S. Hoffman

30. Thermoregulatory Principles

Susi U. Vassallo and Kathleen A. Delaney

SECTION III

SPECIAL POPULATIONS

31. Reproductive and Perinatal Principles

Jeffrey S. Fine

32. Pediatric Principles

Jeffrey S. Fine

33. Geriatric Principles

Judith C. Ahronheim and Mary Ann Howland

34. Postmortem Toxicology

Rama B. Rao and Mark A. Flomenbaum

C2. ORGAN PROCUREMENT FROM POISONED PATIENTS

Rama B. Rao

PART C

THE CLINICAL BASIS OF MEDICAL TOXICOLOGY

SECTION I

A. ANALGESICS AND ANTIINFLAMMATORY MEDICATIONS

CASE STUDY 1

35. Acetaminophen

Robert G. Hendrickson

A3. N-ACETYLCYSTEINE

Robert G. Hendrickson and Mary Ann Howland

36. Colchicine, Podophyllin, and the Vinca Alkaloids

Joshua G. Schier

37. Nonsteroidal Antiinflammatory Drugs

William J. Holubek

38. Opioids

Lewis S. Nelson and Dean Olsen

A4. OPIOID ANTAGONISTS

Lewis S. Nelson and Mary Ann Howland

39. Salicylates

Daniel M. Lugassy

A5. SODIUM BICARBONATE

Paul M. Wax

B. FOOD, DIET, AND NUTRITION

CASE STUDY 2

40. Athletic Performance Enhancers

Susi U. Vassallo

41. Botulism

Howard L. Geyer

A6. BOTULINUM ANTITOXIN

Silas W. Smith and Howard L. Geyer

42. Dieting Xenobiotics and Regimens

Jeanna M. Marraffa

43. Essential Oils

Lauren Kornreich Shawn

44. Food Poisoning

Michael G. Tunik

45. Herbal Preparations

Oliver L. Hung

46. Iron

Jeanmarie Perrone

A7. DEFEROXAMINE

Mary Ann Howland

47. Vitamins

Beth Y. Ginsburg

C. PHARMACEUTICALS

CASE STUDY 3

48. Antiepileptics

Suzanne Doyon

A8. L-CARNITINE

Mary Ann Howland

49. Antihistamines and Decongestants

Sophie Gosselin

A9. PHYSOSTIGMINE SALICYLATE

CONTRIBUTORS

Judith C. Ahronheim, MD, MSJ

Clinical Professor of Medicine
New York Medical College
Valhalla, New York

[Chapter 33](#), “[Geriatric Principles](#)”

Kavita M. Babu, MD

Associate Professor of Emergency Medicine
University of Massachusetts Medical School
Fellowship Director
Division of Medical Toxicology
University of Massachusetts Memorial Medical Center
Worcester, Massachusetts

[Chapter 82](#), “[Hallucinogens](#)”

Theodore C. Bania, MD, MS

Assistant Professor of Clinical Medicine
Columbia University College of Physicians and Surgeons
Director of Toxicology and Research
St. Luke’s-Roosevelt Hospital Center
New York, New York

[Antidotes in Depth](#): A20, “[Intravenous Fat Emulsion](#)”

Fermin Barrueto Jr, MD

Clinical Associate Professor of Emergency Medicine
University of Maryland
Chair, Department of Emergency Medicine
Upper Chesapeake Health Systems
Baltimore, Maryland

[Chapter 115](#), “[Sodium Monofluoroacetate and Fluoroacetamide](#)”

James David Barry, MD

Program Director, Emergency Medicine Residency
Naval Medical Center Portsmouth
Portsmouth, Virginia

[Chapter 59](#), “[Antimalarials](#)”

Michael C. Beuhler, MD

Associate Professor of Emergency Medicine
University of North Carolina at Chapel Hill
Medical Director, Carolinas Poison Center
Charlotte, North Carolina

[Chapter 116, “Phosphorus”](#)

Steven B. Bird, MD

Associate Professor of Emergency Medicine
University of Massachusetts Medical School
Residency Program Director and Vice Chair of Education
University of Massachusetts Memorial Medical Center
Worcester, Massachusetts

[Chapter 93, “Chromium”](#)

Kelly A. Green Boesen, PharmD, BCPS

Clinical Pharmacist
El Rio Community Health Center
Tucson, Arizona
Special Considerations: SC8, “Exotic (Nonnative) Snake Envenomations”

Keith Boesen, PharmD

Instructor
University of Arizona College of Pharmacy
Pharmacist, Managing Director
Arizona Poison and Drug Information Center
Tucson, Arizona
Special Considerations: SC8, “Exotic (Nonnative) Snake Envenomations”

George M. Bosse, MD

Professor of Emergency Medicine
University of Louisville
Medical Director
Kentucky Regional Poison Center
Louisville, Kentucky

[Chapter 53, “Antidiabetics and Hypoglycemics”](#)

Nicole C. Bouchard, MD, FACMT, FRCPC

Assistant Professor of Medicine
Columbia University, College of Physicians and Surgeons
Director of Medical Toxicology
Assistant Site Director
New York-Presbyterian Hospital
New York, New York

[Chapter 56, “Thyroid and Antithyroid Medications”](#)

Jeffrey R. Brubacher, MD, MSc, FRCPC

Assistant Professor
University of British Columbia
Emergency Physician
Vancouver General Hospital
Toxicology Consultant, British Columbia Drug and Poison Information Centre
Vancouver, British Columbia, Canada

[Chapter 62, “ \$\beta\$ -Adrenergic Antagonists”](#)

D. Eric Brush, MD

Associate Professor of Emergency Medicine
University of Massachusetts Medical School
Division of Toxicology
University of Massachusetts Memorial Medical Center
Worcester, Massachusetts

[Chapter 119, “Marine Envenomations”](#)

Michele M. Burns, MD, MPH

Assistant Professor of Pediatrics
Harvard Medical School
Fellowship Director, Harvard Medical Toxicology Fellowship
Medical Director, Regional Center for Poison Control and Prevention
Attending Physician, Emergency Medicine
Boston Children’s Hospital
Boston, Massachusetts

[Chapter 101, “Silver”](#)

Diane P. Calello, MD, FAAP, FACMT

Medical Toxicologist
New Jersey Poison Information and Education System
Rutgers University, New Jersey Medical School
Attending Physician
Morristown Medical Center Residency in Emergency Medicine

[Chapter 96, “Lead”](#)

[Chapter 100, “Selenium”](#)

Louis R. Cantilena, MD, PhD

Professor of Medicine and Pharmacology
Department of Medicine
Uniformed Services University
Bethesda, Maryland

[Chapter 139, “Drug Development, Adverse Drug Events and Postmarketing Surveillance”](#)

Jennifer Lee Carey, MD

Clinical Instructor of Emergency Medicine
University of Massachusetts Medical School
Fellow in Medical Toxicology
University of Massachusetts Memorial Medical Center
Worcester, Massachusetts

[Chapter 82, “Hallucinogens”](#)

Gar Ming Chan, MD, FACEM

Specialist in Emergency Medicine
Launceston General Hospital
Tasmania, Australia

[Chapter 94, “Cobalt”](#)

Yiu-Cheung Chan, MD, MBBS, FRCS (Ed), FHKCEM, FHKAM

Associate Consultant, Director of Toxicology Training

Hong Kong Poison Information Centre

Hong Kong SAR, China

[Chapter 117, “Strychnine”](#)

Nathan P. Charlton, MD

Assistant Professor of Emergency Medicine

Department of Emergency Medicine, Division of Medical Toxicology

University of Virginia School of Medicine

Charlottesville, Virginia

[Chapter 128, “Smoke Inhalation”](#)

Alan N. Charney, MD

Clinical Professor of Medicine

New York University School of Medicine

New York, New York

[Chapter 19, “Fluid, Electrolyte, and Acid–Base Principles”](#)

Betty C. Chen, MD

Acting Instructor

University of Washington School of Medicine, Division of Emergency Medicine

Attending Physician

Harborview Medical Center

Seattle, Washington

[Chapter 60, “Antithrombotics”](#)

William K. Chiang, MD

Associate Professor of Emergency Medicine

New York University School of Medicine

Attending Physician

Bellevue Hospital Center and New York University Langone Medical Center

New York, New York

[Chapter 26, “Otolaryngologic Principles”](#)

Jason Chu, MD

Assistant Professor of Clinical Medicine

Columbia University College of Physicians and Surgeons

Attending Physician

St. Luke’s-Roosevelt Hospital Center

New York, New York

[Chapter 21, “Genitourinary Principles”](#)

[Chapter 54, “Antimigraine Medications”](#)

Richard J. Church, MD, FACEP

Assistant Professor of Emergency Medicine

University of Massachusetts Medical School

Assistant Director, Emergency Medicine Residency Program
University of Massachusetts Memorial Medical Center
Worcester, Massachusetts
[Chapter 20, “Gastrointestinal Principles”](#)

Cathleen Clancy, MD, FACMT

Associate Professor
Department of Emergency Medicine
George Washington University Medical Center
Associate Medical Director
National Capital Poison Center
Washington, District of Columbia
Attending Emergency Medicine Physician
Bethesda Naval Emergency Department
Walter Reed National Military Medical Center
Bethesda, Maryland

[Chapter 16, “Electrophysiologic and Electrocardiographic Principles”](#)

Richard F. Clark, MD

Professor of Emergency Medicine
University of California, San Diego
Director, Division of Medical Toxicology
University of California San Diego Medical Center
San Diego, California

[Antidotes in Depth: A34, “Antivenom: Spider”](#)

[Antidotes in Depth: A35, “Antivenom: Scorpion”](#)

Steven C. Curry, MD

Professor of Medicine
University of Arizona College of Medicine–Phoenix
Center for Toxicology and Pharmacology Education and Research
University of Arizona
Director, Department of Medical Toxicology
Banner Good Samaritan Medical Center
Phoenix, Arizona

[Chapter 14, “Neurotransmitters and Neuromodulators”](#)

John A. Curtis Jr, MD

Assistant Professor of Emergency Medicine
Drexel University College of Medicine
Philadelphia, Pennsylvania
Cheshire Medical Center Dartmouth-Hitchcock Keene
Keene, New Hampshire

[Chapter 99, “Nickel”](#)

Michael A. Darracq, MD, MPH

Assistant Professor of Emergency Medicine

University of California, San Francisco Fresno Medical Education Program
Department of Emergency Medicine
Fresno, California
California Poison Control System
San Diego, California

[Antidotes in Depth: A34](#), “Antivenom: Spider”

[Antidotes in Depth: A35](#), “Antivenom: Scorpion”

Andrew Dawson, MBBS, FRACP

Clinical Professor of Medicine
University of Sydney
Sydney, Australia
Senior Staff Specialist
New South Wales Poisons Information Centre
Westmead, New South Wales, Australia

[Chapter 110](#), “Barium”

Kathleen A. Delaney, MD

Clinical Professor, Division of Emergency Medicine
University of Texas Southwestern Medical School
Dallas, Texas

[Chapter 13](#), “Biochemical and Metabolic Principles”

[Chapter 23](#), “Hepatic Principles”

[Chapter 30](#), “Thermoregulatory Principles”

[Antidotes in Depth: A12](#), “Dextrose (D-Glucose)”

Francis Jerome DeRoos, MD

Associate Professor of Emergency Medicine
Perelman School of Medicine at the University of Pennsylvania
Residency Director
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

[Chapter 61](#), “Calcium Channel Blockers”

[Chapter 63](#), “Miscellaneous Antihypertensives and Pharmacologically Related Agents”

Suzanne Doyon, MD, FACEP, FACMT

Adjunct Associate Professor
University of Maryland School of Pharmacy
Medical Director
Maryland Poison Center
Baltimore, Maryland

[Chapter 48](#), “Antiepileptics”

Dainius A. Drukteinis, MD, JD, FACEP

Assistant Clinical Professor of Emergency Medicine
University of South Florida
Associate Medical Director

Tampa General Hospital

Tampa, Florida

[Chapter 141, “Risk Management and Legal Principles”](#)

Michael Eddleston, MD, PhD, MRCP

Professor of Clinical Toxicology

University of Edinburgh

Consultant in Clinical Toxicology

Royal Infirmary of Edinburgh

Edinburgh, United Kingdom

[Chapter 113, “Insecticides: Organic Phosphorus Compounds and Carbamates”](#)

Kyle B. Enfield, MD, MS

Assistant Professor of Medicine

University of Virginia School of Medicine

Medical Director Medical Intensive Care Unit

Assistant Hospital Epidemiologist

University of Virginia Health System

Charlottesville, Virginia

[Chapter 11, “Use of the Intensive Care Unit”](#)

Brenna M. Farmer, MD

Assistant Professor of Medicine

Weill Cornell Medical College of Cornell University

Attending Physician

New York Presbyterian Hospital

Weill Cornell Medical Center

New York, New York

[Chapter 83, “G-Hydroxybutyric Acid”](#)

[Chapter 87, “Aluminum”](#)

[Chapter 140, “Medication Safety and Adverse Drug Events”](#)

Jeffrey S. Fine, MD

Assistant Professor of Emergency Medicine and Pediatrics

New York University School of Medicine

Attending Physician

Bellevue Hospital Center and New York University Langone Medical Center

New York, New York

[Chapter 31, “Reproductive and Perinatal Principles”](#)

[Chapter 32, “Pediatric Principles”](#)

Mark A. Flomenbaum, MD, PhD

Lecturer in Microbiology and Immunology

Harvard Medical School

Deputy Chief Medical Examiner

Office of Chief Medical Examiner, State of Maine

Boston, Massachusetts

[Chapter 34, “Postmortem Toxicology”](#)

Jessica A. Fulton, DO

Attending Physician
Grandview Hospital
Sellersville, Pennsylvania

[Chapter 106, “Caustics”](#)

Howard L. Geyer, MD, PhD

Assistant Professor of Neurology
Albert Einstein College of Medicine of Yeshiva University
Director, Division of Movement Disorders
Montefiore Medical Center
Bronx, New York

[Chapter 41, “Botulism”](#)

[Antidotes in Depth: A6, “Botulinum Antitoxin”](#)

Marc Ghannoum, MD

Associate Professor of Medicine
University of Montreal
Verdun Hospital
Montreal, Canada

[Chapter 10, “Principles and Techniques Applied to Enhance Elimination”](#)

[Chapter 28, “Renal Principles”](#)

Beth Y. Ginsburg, MD
Assistant Professor of Emergency Medicine
Icahn School of Medicine at Mount Sinai
Attending Physician
Elmhurst Hospital Center
Elmhurst, New York

[Chapter 47, “Vitamins”](#)

Jeffrey A. Gold, MD

Associate Professor of Medicine
Program Director, Pulmonary Critical Care
Associate Director, Adult Cystic Fibrosis Center
Oregon Health and Sciences University
Portland, Oregon

[Chapter 81, “Ethanol Withdrawal”](#)

David S. Goldfarb, MD, FACP

Professor of Medicine and Physiology
New York University School of Medicine
Chief, Nephrology
New York Harbor VA Healthcare System
Clinical Chief, Nephrology Division
New York University Langone Medical Center

New York, New York

[Chapter 10, “Principles and Techniques Applied to Enhance Elimination”](#)

[Chapter 28, “Renal Principles”](#)

Lewis R. Goldfrank, MD, FAACT, FAAEM, FACEP, FACMT, FACP

Herbert W. Adams Professor and Chair

Department of Emergency Medicine

New York University School of Medicine

Director, Emergency Medicine

Bellevue Hospital Center and New York University Langone Medical Center

Medical Director, New York City Poison Center

New York, New York

[Chapter 3, “Initial Evaluation of the Patient: Vital Signs and Toxic Syndromes”](#)

[Chapter 4, “Principles of Managing the Acutely Poisoned or Overdosed Patient”](#)

[Chapter 120, “Mushrooms”](#)

[Chapter 121, “Plants”](#)

Sophie Gosselin, MD, CSPQ, FRCPC

Associate Professor

Department of Medicine

Faculty of Medicine, McGill University

McGill University Health Centre and Centre Antipoison du Québec

Montréal, Québec, Canada

[Chapter 49, “Antihistamines and Decongestants”](#)

Kimberlie A. Graeme, MD

Clinical Associate Professor of Emergency Medicine

University of Arizona, College of Medicine–Phoenix

Attending Toxicologist

Banner Good Samaritan Medical Center

Attending Toxicologist, Phoenix Children’s Hospital

Phoenix, Arizona

[Chapter 14, “Neurotransmitters and Neuromodulators”](#)

Howard A. Greller, MD

Associate Professor of Emergency Medicine

Icahn School of Medicine at Mount Sinai

Attending Physician

Division of Medical Toxicology

Department of Emergency Medicine

Mount Sinai Medical Center

Associate Director, Upper West Side Urgent Care Center

New York, New York

[Chapter 72, “Lithium”](#)

Anne-Bolette J. Gude, MD

Specialist, Clinical Pharmacology

Danish Medical Association

Danish Society of Clinical Pharmacology

Copenhagen, Denmark

[Chapter 8, “Techniques Used to Prevent Gastrointestinal Absorption”](#)

David D. Gummin, MD, FAACT, FACEP, FACMT

Professor, Medical College of Wisconsin

Section Chief, Medical Toxicology

Medical Director, Wisconsin Poison Center

Milwaukee, Wisconsin

[Chapter 108, “Hydrocarbons”](#)

Amit K. Gupta, MD

Assistant Professor of Emergency Medicine

SUNY Downstate Medical Center

Attending Physician

Staten Island University Hospital

Staten Island, New York

[Chapter 79, “Disulfiram and Disulfiramlike Reactions”](#)

Jason B. Hack, MD

Associate Professor of Emergency Medicine

Program Director, Medical Toxicology

Brown University, Warren Alpert Medical School

Rhode Island Hospital

Providence, Rhode Island

[Chapter 65, “Cardioactive Steroids”](#)

David A. Haggerty, MD, FAAEM

Chairman, Department of Emergency Medicine

Good Samaritan Hospital

Lebanon, PA

Pinnacle Health System

Division of Medical Toxicology

Department of Internal Medicine

Harrisburg, PA

[Chapter 99, “Nickel”](#)

In-Hei Hahn, MD

Assistant Professor

University of Vermont Department of Surgery

Danbury Hospital Center, Department of Emergency Medicine

Danbury, Connecticut

Associate Attending, Emergency Medicine

St. Luke’s-Roosevelt Hospital Center

New York, New York

[Chapter 118, “Arthropods”](#)

Richard J. Hamilton, MD

Professor and Chairman of Emergency Medicine
Drexel University College of Medicine
Philadelphia, Pennsylvania

[Chapter 15, “Withdrawal Principles”](#)

Robert G. Hendrickson, MD, FAACT, FACMT

Associate Professor of Emergency Medicine
Oregon Health and Science University
Program Director, Fellowship in Medical Toxicology
Medical Director, Emergency Management
Associate Medical Director, Oregon Poison Center
Portland, Oregon

[Chapter 35, “Acetaminophen”](#)

[Antidotes in Depth: A3, “N-Acetylcysteine”](#)

Fred M. Henretig, MD

Professor of Pediatrics and Emergency Medicine
Perelman School of Medicine at the University of Pennsylvania
Director, Section of Clinical Toxicology
Children’s Hospital of Philadelphia
Philadelphia, Pennsylvania

[Chapter 96, “Lead”](#)

Christina H. Hernon, MD

Assistant Professor of Emergency Medicine
University of Massachusetts Medical School
Division of Medical Toxicology
University of Massachusetts Memorial Medical Center
Worcester, Massachusetts

[Chapter 58, “Antituberculous Medications”](#)

Robert A. Hessler, MD, PhD

Associate Professor of Emergency Medicine
New York University School of Medicine
Attending Physician
Bellevue Hospital Center and New York University Langone Medical Center and Veterans Administration Medical Center, Manhattan
New York, New York

[Chapter 17, “Cardiologic Principles II: Hemodynamics”](#)

Lotte C. G. Hoegberg, MS (Pharm), PhD

Pharmacist, Danish Poisons Information Centre
Department of Anaesthesiology and Intensive Care Medicine
Copenhagen University Hospital, Bispebjerg
Copenhagen, Denmark

[Chapter 8, “Techniques Used to Prevent Gastrointestinal Absorption”](#)

Robert J. Hoffman, MD, MS

Director, Clinical Toxicology
Sidra Medical and Research Center
Doha, Qatar

[Chapter 66, “Methylxanthines and Selective \$\beta_2\$ -Adrenergic Agonists”](#)

Robert S. Hoffman, MD, FAACT, FACMT, FRCP Edin, FEAPCCT

Professor of Emergency Medicine and Medicine Director, Division of Medical Toxicology
New York University School of Medicine
Attending Physician, Emergency Medicine
Bellevue Hospital Center and New York University Langone Medical Center
Consultant, New York City Poison Center
New York, New York

[Chapter 3, “Initial Evaluation of the Patient: Vital Signs and Toxic Syndromes”](#)

PREFACE

Goldfrank's Toxicologic Emergencies is a multiauthored text of approximately 2000 pages prepared by using the educational and management principles we apply at the New York City Poison Center and at our clinical sites. In this tenth edition of Goldfrank's Toxicologic Emergencies, we proudly offer readers an approach to medical toxicology using evidence-based principles viewed through the lens of an active bedside clinical practice.

Some would ask why create textbooks and e-books in an era when podcasts and blogs appear so successful. We still believe that the slow, thoughtful, rigorous development by a team of authors and editors that is required to create and revise this text is necessary to appropriately analyze the most complex problems that challenge our daily practices. Although in our field we have made great progress, the level of uncertainty remains substantial. We have attempted to integrate the collaborative wisdom of many experts from diverse backgrounds into the text to provide the most up to date information. We offer our readers the evidence, shared thoughts, and commitments necessary to arrive at a decision. Evidence is created not only with randomized clinical trials, observational studies, case control studies, and case reports, but also with the insights of five toxicologists who have worked together for decades, along with the gifted scholars we selected as authors. We have worked together defining and redefining the scope and context of chapters, Antidotes in Depth, and Special Considerations. We then shared our ideas with many respected toxicologists, thus creating new chapters that these toxicologists have revised by adding information that has come to light over the last 4 years. In this way, knowledge from their work in toxicology and related disciplines is merged with ours, allowing us to create chapters that represent our collective thoughts. This iterative process is continued until the authors and editors are satisfied that we have closely approximated the best strategy to evaluate and care for poisoned or overdosed patients. This is a fascinating process. Because we occasionally disagree, we then reread, research, look for special cases, and reflect on a final version with our authors. By reviewing the quality of each chapter, we thus create, recreate, and reformat.

In this edition, we have reintroduced the patient into the text. These are the patients who wake us up at night. Such patients, whose signs and symptoms might be related to the whole book or to several chapters, serve to return us to focus on the unknown, the differential diagnosis, and problem solving and include cases representative of our work. Patients with a pesticide exposure, bradycardia, metabolic acidosis, medication error, seizures, as well as coma or agitation and hyperthermia, are offered as examples for contemplation. We believe that analyzing the care of these complex, undifferentiated patients will help you as much as they have helped us and those who read the first edition of this book. These cases act as the building blocks for chapters in this edition and represent provocative introductions to several sections of this text. We have demonstrated our thought processes so that you can read, think, criticize, and communicate. This classic Socratic development of knowledge and improvement of clinical decision making will foster problem solving, initiate creative investigation, and improve care. We hope to facilitate your participation in the intellectual process that we believe to be essential in order to create a fine book for thoughtful readers who must render exceptional attention to their patients. The cases serve as the transition between the patient and population. You can switch your role from the medical or clinical toxicologist at the bedside to the toxicologist serving the public needs of a community. Our hope is that these cases recreate the clinicians experience of the thinking that occurs before the action.

The other major change in this edition has occurred in one of our most valued sections—the Antidotes in Depth. Mary Ann Howland, PharmD, has worked on improving the presentation of each of the Antidotes in Depth with an even more rigorous format. Her wisdom in this area is unmatched, as she has nurtured these key toxicologic elements since the third edition of this textbook. In this tenth edition, Silas W. Smith, MD, has collaborated with her as an Associate Editor for the Antidotes in Depth section. We are sure that you will appreciate the reorganization of this section, which will enhance your ability to use the material the Antidotes in Depth provide. Their collaboration should be a great asset to the reader.

Robert S. Hoffman

Mary Ann Howland

Neal A. Lewin

Lewis S. Nelson

Lewis R. Goldfrank

ACKNOWLEDGMENTS

We are grateful to Joan Demas, who worked extensively with the local, national, and international authors to ensure that their ideas were effectively expressed. She has assisted all of us in checking the facts, finding essential references, improving the structure and function of our text while dedicating her efforts to ensuring the precision and rigor of the text for her fourth consecutive edition. She has helped authors new and old master their rigorous commitment with the skill of a great publishing professional. The authors' and editors' work is better because of her devotion to excellence, calm demeanor in the face of editorial chaos, and consistent presence throughout each stage of the production of this text. We are deeply appreciative of the wonderful effort she provides for our readers and colleagues.

The many letters and verbal communications we have received with the reviews of the previous editions of this book continue to improve our efforts. We are deeply indebted to our friends, associates, and students, who stimulated us to begin this book with their questions and then faithfully criticized our answers.

We thank the many volunteers, students, librarians, and particularly the St. John's University College of Pharmacy students and drug information staff who provide us with vital technical assistance in our daily attempts to deal with toxicologic emergencies.

Mary Ann Howland, PharmD, gratefully acknowledges the helpful comments of Parshotam Madam, PhD, Department of Pharmaceutical Sciences, St. John's University College of Pharmacy and Health Sciences in the preparation of her chapter on Pharmacokinetic and Toxicokinetic Principles.

No words can adequately express our indebtedness to the many authors who worked on earlier editions of many of the chapters in this book. As different authors write and rewrite topics with each new edition, we recognize that without the foundation work of their predecessors this book would not be what it is today.

We appreciate the creative and rigorous advances in design and scientific art that the McGraw-Hill team, led by Armen Ovsepyan, have added to the text. The devotion to the creation of high-quality art graphics and tables is greatly appreciated. The support for excellence in this edition was facilitated by the constant vigilance of Executive Editor, Michael Weitz.

We appreciate the calm, thoughtful, and cooperative spirit of Karen Edmonson at McGraw-Hill. Her intelligence and ever vigilant commitment to our efforts has been wonderful. We are pleased with the creative developmental editorial efforts of Christie Naglieri. The organized project management by Tania Andrabi has found errors hiding throughout our pages. Her carefully posed questions have facilitated the process of correcting the text. It has been a pleasure to have her assistance. We greatly appreciate the compulsion and rigor that Michael Ferreira has applied to make this edition's index one of unique value. We appreciate the work of Catherine Saggese in ensuring the quality of production in the finished work.

1 HISTORICAL PRINCIPLES AND PERSPECTIVES

Paul M. Wax

The term poison first appeared in the English literature around the year 1225 A.D. to describe a potion or draught that was prepared with deadly ingredients.^{8,147} The history of poisons and poisoning, however, dates back thousands of years. Throughout the millennia, poisons have played an important role in human history—from political assassination in Roman times, to weapons of war, to contemporary environmental concerns, and to weapons of terrorism.

This chapter offers a perspective on the impact of poisons and poisoning on history. It also provides a historic overview of human understanding of poisons and the development of toxicology from antiquity to the present. The development of the modern poison center, the genesis of the field of medical toxicology, and the recent increasing focus on medication errors are examined. [Chapter 2](#) describes poison plagues and unintentional disasters throughout history and examines the societal consequences of these unfortunate events. An appreciation of past failures and mistakes in dealing with poisons and poisoning promotes a keener insight and a more critical evaluation of present-day toxicologic issues and helps in the assessment and management of future toxicologic problems.

POISONS, POISONERS, AND ANTIDOTES OF ANTIQUITY

The earliest poisons consisted of plant extracts, animal venoms, and minerals. They were used for hunting, waging war, and sanctioned and unsanctioned executions. The Ebers Papyrus, an ancient Egyptian text written circa 1500 B.C. that is considered to be among the earliest medical texts, describes many ancient poisons, including aconite, antimony, arsenic, cyanogenic glycosides, hemlock, lead, mandrake, opium, and wormwood.^{97,147} These poisons were thought to have mystical properties, and their use was surrounded by superstition and intrigue. Some agents, such as the Calabar bean (*Physostigma venenosum*) containing physostigmine, were referred to as “ordeal poisons.” Ingestion of these substances was believed to be lethal to the guilty and harmless to the innocent.¹²³ The “penalty of the peach” involved the administration of peach pits, which we now know contain the cyanide precursor amygdalin, as an ordeal poison. Magicians, sorcerers, and religious figures were the toxicologists of antiquity. The Sumerians, in circa 4500 B.C., were said to worship the deity Gula, who was known as the “mistress of charms and spells” and the “controller of noxious poisons” ([Table 1–1](#)).¹⁴⁷

TABLE 1–1. Important Early Figures in the History of Toxicology

<i>Person</i>	<i>Date</i>	<i>Importance</i>
Gula	ca. 4500 B.C.	First deity associated with poisons
Shen Nung	ca. 2000 B.C.	Chinese emperor who experimented with poisons and antidotes and wrote treatise on herbal medicine
Homer	ca. 850 B.C.	Wrote how Ulysses anointed arrows with the venom of serpents
Aristotle	384–322 B.C.	Described the preparation and use of arrow poisons
Theophrastus	ca. 370–286 B.C.	Referred to poisonous plants in <i>De Historia Plantarum</i>
Socrates	ca. 470–399 B.C.	Executed by poison hemlock
Nicander	204–135 B.C.	Wrote two poems, <i>Theriaca</i> and <i>Alexipharmaca</i> , that are among the earliest works on poisons
King Mithridates VI	ca. 132–63 B.C.	Fanatical fear of poisons; developed mithradatum, one of the first universal antidotes
Sulla	81 B.C.	Issued <i>Lex Cornelia</i> , the first antipoisoning law
Cleopatra	69–30 B.C.	Committed suicide with deliberate cobra envenomation
Andromachus	37–68 A.D.	Refined mithradatum; known as the Theriac of Andromachus
Dioscorides	40–80 A.D.	Wrote <i>Materia Medica</i> , which classified poisons by animal, vegetable, and mineral
Galen	ca. 129–200 A.D.	Prepared “nut theriac” for Roman emperors, a remedy against bites, stings, and poisons; wrote <i>De Antidotis I</i> and <i>II</i> , which provided recipes for different antidotes, including mithradatum and panacea
Ibn Wahshiya	9th century	Famed Arab toxicologist; wrote toxicology treatise <i>Book on Poisons</i> , combining contemporary science, magic, and astrology
Moses Maimonides	1135–1204	Wrote <i>Treatise on Poisons and Their Antidotes</i>
Petrus Abbonus	1250–1315	Wrote <i>De Venenis</i> , major work on poisoning

Arrow and Dart Poisons

The prehistoric Masai hunters of Kenya, who lived 18,000 years ago, used arrow and dart poisons to increase the lethality of their weapons.²⁰ One of these poisons appears to have consisted of extracts of *Strophanthus* species, an indigenous plant that contains strophanthin, a digitalislike substance.⁹⁷ Cave paintings of arrowheads and spearheads reveal that these weapons were crafted with small depressions at the end to hold the poison.¹⁴⁸ In fact, the term toxicology is derived from the Greek terms *toxikos* (“bow”) and *toxikon* (“poison into which arrowheads are dipped”).^{6,148}

References to arrow poisons are cited in a number of other important literary works. The ancient Indian text *Rig Veda*, written in the 12th century B.C., refers to the use of *Aconitum* species for arrow poisons.²⁰ In the *Odyssey*, Homer (ca. 850 B.C.) wrote that Ulysses anointed his arrows with a variety of poisons, including extracts of *Helleborus orientalis* and snake venoms. The writings of Ovid (43 B.C.–18 A.D.), describe weapons poisoned with the blood of serpents.¹⁵⁵

Classification of Poisons

The first attempts at poison identification and classification and the introduction of the first antidotes took place during Greek and Roman times. An early categorization of poisons divided them into fast poisons, such as strychnine, and slow poisons, such as arsenic. In his treatise, *Materia Medica*, the Greek physician Dioscorides (40–80 A.D.) categorized poisons by their origin—animal, vegetable, or mineral.¹⁴⁸ This categorization remained the standard classification for the next 1500 years.¹⁴⁸

Animal Poisons. Animal poisons usually referred to the venom from poisonous animals. Although the venom from poisonous snakes has always been among the most commonly feared poisons, poisons from toads, salamanders, jellyfish, stingrays, and sea hares are often as lethal. Nicander of Colophon (204–135 B.C.), a Greek poet and physician who is considered to be one of the earliest toxicologists, experimented with animal poisons on condemned criminals.¹³⁴ Nicander's poems *Theriaca* and *Alexipharmaca* are considered to be the earliest extant Greek toxicologic texts, describing the presentations and treatment of poisonings from animal xenobiotics.¹⁴⁷ A notable fatality from the effects of an animal xenobiotic was Cleopatra (69–30 B.C.), who reportedly committed suicide by deliberately falling on an asp.⁷⁵

Vegetable Poisons. Theophrastus (ca. 370–286 B.C.) described vegetable poisons in his treatise *De Historia Plantarum*.⁷⁶ Notorious poisonous plants included *Aconitum* species (monkshood aconite), *Conium maculatum* (poison hemlock), *Hyoscyamus niger* (henbane), *Mandragora officinarum* (mandrake), *Papaver somniferum* (opium poppy), and *Veratrum album* (hellebore). Aconite was among the most frequently encountered poisonous plants and was described as the “queen mother of poisons.”¹⁴⁷ Hemlock was the official poison used by the Greeks and was used in the execution of Socrates (ca. 470–399 B.C.) and many others.¹³⁶ Poisonous plants used in India at this time included *Cannabis indica* (marijuana), *Croton tiglium* (croton oil), and *Strychnos nux vomica* (poison nut, strychnine).⁷⁶

Mineral Poisons. The mineral poisons of antiquity consisted of the metals antimony, arsenic, lead, and mercury. Undoubtedly, the most famous of these was lead. Lead was discovered as early as 3500 B.C. Although controversy continues about whether an epidemic of lead poisoning among the Roman aristocracy contributed to the fall of the Roman Empire, lead was certainly used extensively during this period.^{55,112} In addition to its considerable use in plumbing, lead was also used in the production of food and drink containers.⁶² It was common practice to add lead directly to wine or to intentionally prepare the wine in a lead kettle to improve its taste. Not surprisingly, chronic lead poisoning became widespread. Nicander described the first case of lead poisoning in the 2nd century B.C.¹⁵¹ Dioscorides, writing in the 1st century A.D., noted that fortified wine was “most hurtful to the nerves.”¹⁵¹ Lead-induced gout (“saturnine gout”) may have also been widespread among the Roman elite.¹¹²

Gases. Although not animal, vegetable, or mineral in origin, the toxic effects of gases were also appreciated during antiquity. In the 3rd century B.C., Aristotle commented that “coal fumes (carbon monoxide) lead to a heavy head and death,”⁷³ and Cicero (106–43 B.C.) referred to the use of coal fumes in suicides and executions.

Poisoners of Antiquity

Given the increasing awareness of the toxic properties of some naturally occurring xenobiotics and the lack of analytical detection techniques, homicidal poisoning was common during Roman times. During this period, members of the aristocracy commonly used “tasters” to shield themselves from potential poisoners, a practice also in vogue during the reign of Louis XIV in 16th century France.¹⁵⁵

One of the most infamous poisoners of ancient Rome was Locusta, who was known to experiment on slaves with poisons that included aconite, arsenic, belladonna, henbane, and poisonous fungi. In 54 A.D., Nero's mother, Agrippina, hired Locusta to poison Emperor Claudius (Agrippina's husband and Nero's stepfather) as part of a scheme to make Nero emperor. As a result of these activities, Claudius, who was a great lover of mushrooms, died from *Amanita phalloides* poisoning.¹⁸ and in the next year, Britannicus (Nero's stepbrother) also became one of Locusta's victims. In his case, Locusta managed to fool the taster by preparing unusually hot soup that required additional cooling after the soup had been officially tasted. At the time of cooling, the poison was surreptitiously slipped into the soup. Almost immediately after drinking the soup, Britannicus collapsed and died. The exact poison remains in doubt, although some authorities suggest that it was a cyanogenic glycoside.¹³⁹

Early Quests for the Universal Antidote

The recognition, classification, and use of poisons in ancient Greece and Rome were accompanied by an intensive search for a universal antidote. In fact, many of the physicians of this period devoted significant parts of their careers to this endeavor.¹⁴⁷ Mystery and superstition surrounded the origins and sources of these proposed antidotes. One of the earliest specific references to a protective agent can be found in Homer's *Odyssey*, when Ulysses is advised to protect himself by taking the antidote “moli.” Recent speculation suggests that moli referred to *Galanthus nivalis*, which contains a cholinesterase inhibitor. This agent could have been used as an antidote against poisonous plants such as *Datura stramonium* (jimsonweed) that contain the anticholinergic alkaloids scopolamine, atropine, and hyoscyamine.¹²⁰

Theriaks and the Mithradatum. The Greeks referred to the universal antidote as the alexipharmaca or theriac.^{77,147} The term alexipharmaca was derived from the words alexipharmakos (“which keeps off poison”) and antipharmakon (“antidote”). Over the years, alexipharmaca was increasingly used to refer to a method of treatment, such as the induction of emesis by using a feather. Theriac, which originally had referred to poisonous reptiles or wild beasts, was later used to refer to the antidotes. Consumption of the early theriacs (ca. 200 B.C.) was reputed to make people “poison-proof” against bites of all venomous animals except the asp. Their ingredients included aniseed, anmi, apoponax, fennel, meru, parsley, and wild thyme.¹⁴⁷

The quest for the universal antidote was epitomized by the work of King Mithradates VI of Pontus (132–63 B.C.).⁷⁴ After repeatedly being subjected to poisoning attempts by his enemies during his youth, Mithradates sought protection by the development of universal antidotes. To find the best antidote, he performed acute toxicity experiments on criminals and slaves. The theriac he concocted, known as the “mithradatum,” contained a minimum of 36 ingredients and was thought to be protective against aconite, scorpions, sea slugs, spiders, vipers, and all other poisonous substances. Mithradates took his concoction every day. Ironically, when an old man, Mithradates attempted suicide by poison but supposedly was unsuccessful because he had become poison-proof. Having failed at self-poisoning, Mithradates was compelled to have a soldier kill him with a sword. Galen described Mithradates’ experiences in a series of three books: *De Antidotis I*, *De Antidotis II*, and *De Theriaca ad Pisonem*.^{74,152}

The Theriac of Andromachus, also known as the “Venice treacle” or “galene,” is probably the most well known theriac.⁶⁴ According to Galen, this preparation, formulated during the 1st century A.D., was considered an improvement over the mithradatum.¹⁴⁶ It was prepared by Andromachus (37–68 A.D.), physician to Emperor Nero. Andromachus added to the mithradatum ingredients such as the flesh of vipers, squills, and generous amounts of opium.¹⁵⁸ Other ingredients were removed. Altogether, 73 ingredients were required. It was advocated to “counteract all poisons and bites of venomous animals,” as well as a host of other medical problems, such as colic, dropsy, and jaundice, and it was used both therapeutically and prophylactically.^{147,152} As evidence of its efficacy, Galen demonstrated that fowl receiving poison followed by theriac had a higher survival rate than fowl receiving poison alone.¹⁴⁷ It is likely, however, that the scientific rigor and methodology used differed from current scientific practice.

By the Middle Ages, the Theriac of Andromachus contained more than 100 ingredients. Its synthesis was quite elaborate; the initial phase of production lasted months followed by an aging process that lasted years, somewhat similar to that of vintage wine.⁹² The final product was often more solid than liquid in consistency.

Other theriac preparations were named after famous physicians (Damocrates, Nicolaus, Amando, Arnould, and Abano) who contributed additional ingredients to the original formulation. Over the centuries, certain localities were celebrated for their own peculiar brand of theriac. Notable centers of theriac production included Bologna, Cairo, Florence, Genoa, Istanbul, and Venice. At times, theriac production was accompanied by great fanfare. For example, in Bologna, the mixing of the theriac could take place only under the direction of the medical professors at the university.¹⁴⁷

Whether these preparations were of actual benefit is uncertain. Some suggest that the theriac may have had an antiseptic effect on the gastrointestinal (GI) tract, but others state that the sole benefit of the theriac derived from its formulation with opium.⁹² Theriacs remained in vogue throughout the Middle Ages and Renaissance, and it was not until 1745 that their efficacy was finally questioned by William Heberden in *Antitheriaka: An Essay on Mithradatum and Theriaca*.⁷⁴ Nonetheless, pharmacopeias in France, Spain, and Germany continued to list these agents until the last quarter of the 19th century, and theriac was still available in Italy and Turkey in the early 20th century.^{19,92}

Sacred Earth. Beginning in the 5th century B.C., an adsorbent agent called terra sigillata was promoted as a universal antidote. This xenobiotic, also known as the “sacred sealed earth,” consisted of red clay that could be found on only one particular hill on the Greek island of Lemnos. Perhaps somewhat akin to the 20th-century “universal antidote,” it was advocated as effective in counteracting all poisons.¹⁴⁷ With great ceremony, once per year, the terra sigillata was retrieved from this hill and prepared for subsequent use. According to Dioscorides, this clay was formulated with goat’s blood to make it into a paste. At one time, it was included as part of the Theriac of Andromachus. Demand for terra sigillata continued into the 15th century. Similar antidotal clays were found in England, Italy, Malta, and Silesia.¹⁴⁷

Charms. Charms, such as toadstones, snakestones, unicorn horns, and bezoar stones, were also promoted as universal antidotes. Toadstones, found in the heads of old toads, were reputed to have the capability to extract poison from the site of a venomous bite or sting. In addition, the toadstone was supposedly able to detect the mere presence of poison by producing a sensation of heat upon contact with a poisonous substance.¹⁴⁷

Similarly, snakestones extracted from the heads of cobras (known as piedras della cobra de Capelos) were also reported to have magical qualities.¹⁴ The 17th-century Italian philosopher Athanasius Kircher (1602–1680) became an enthusiastic supporter of snakestone therapy for the treatment of snakebite after conducting experiments demonstrating the antidotal attributes of these charms “in front of amazed spectators.” Kircher attributed the efficacy of the snakestone to the theory of “attraction of like substances.” Francesco Redi (1626–1698), a court physician and contemporary of Kircher, debunked this quixotic approach. A harbinger of future experimental toxicologists, Redi was unwilling to accept isolated

case reports and field demonstrations as proof of the utility of the snakestone. Using a considerably more rigorous approach, *provando et riprovando* (by testing and retesting), Redi assessed the antidotal efficacy of snakestone on different animal species and different xenobiotics and failed to confirm any benefit.¹⁴

Much lore has surrounded the antidotal effects of the mythical unicorn horn. Ctesias, writing in 390 B.C., was the first to chronicle the wonders of the unicorn horn, claiming that drinking water or wine from the “horn of the unicorn” would protect against poison.¹⁴⁷ The horns were usually narwhal tusks or rhinoceros horns, and during the Middle Ages, the unicorn horn may have been worth as much as 10 times the price of gold. Similar to the toadstone, the unicorn horn was used both to detect poisons and to neutralize them. Supposedly, a cup made of unicorn horn would sweat if a poisonous substance was placed in it.⁹⁰ To give further credence to its use, a 1593 study on arsenic-poisoned dogs reportedly showed that the horn was protective.⁹⁰

Bezoar stones, also touted as universal antidotes, consisted of stomach or intestinal calculi formed by the deposition of calcium phosphate around a hair, fruit pit, or gallstone. They were removed from wild goats, cows, and apes and administered orally to humans. The Persian name for the bezoar stone was *pad zahr* (“expeller of poisons”); the ancient Hebrews referred to the bezoar stone as *bel Zaard* (“every cure for poisons”). Over the years, regional variations of bezoar stones were popularized, including an Asian variety from wild goat of Persia, an Occidental variety from llamas of Peru, and a European variety from chamois of the Swiss mountains.^{50,147}

OPIUM, COCA, CANNABIS, AND HALLUCINOGENS IN ANTIQUITY

Although it was not until the mid-19th century that the true perils of opiate addiction were first recognized, juice from the *Papaver somniferum* was known for its medicinal value in Egypt at least as early as the writing of the Ebers Papyrus in 1500 B.C. Egyptian pharmacologists of that time reportedly recommended opium poppy extract as a pacifier for children who exhibited incessant crying.¹³³ In Ancient Greece, Dioscorides and Galen were early advocates of opium as a therapeutic xenobiotic. During this time, it was also used as a means of suicide. Mithradates’ lack of success in his own attempted suicide by poisoning may have been the result of an opium tolerance that had developed from previous repetitive use.¹³³ One of the earliest descriptions of the abuse potential of opium is attributed to Epistratos (304–257 B.C.), who criticized the use of opium for earache because it “dulled the sight and is a narcotic.”¹³³

Cocaine use dates back to at least 300 B.C., when South American Indians reportedly chewed coca leaves during religious ceremonies.¹⁰⁶ Chewing coca to increase work efficacy and to elevate mood has remained commonplace in some South American societies for thousands of years. An Egyptian mummy from about 950 B.C. revealed significant amounts of cocaine in the stomach and liver, suggesting oral use of cocaine occurred during this time period.¹¹⁰ Large amounts of tetrahydrocannabinol (THC) were also found in the lung and muscle of the same mummy. Another investigation of 11 Egyptian (1079 B.C.–395 A.D.) and 72 Peruvian (200–1500 A.D.) mummies found cocaine, thought to be indigenous only to South America, and hashish, thought to be indigenous only to Asia, in both groups.¹¹⁹

Cannabis use in China dates back even further, to around 2700 B.C., when it was known as the “liberator of sin.”¹⁰⁶ In India and Iran, cannabis was used as early as 1000 B.C. as an xenobiotic known as *bang*.¹⁰⁹ Other currently abused xenobiotics that were known to the ancients include cannabis, hallucinogenic mushrooms, nutmeg, and peyote. As early as 1300 B.C., Peruvian Indian tribal ceremonies included the use of mescaline-containing San Pedro cacti.¹⁰⁶ The hallucinogenic mushroom *Amanita muscaria*, known as “fly agaric,” was used as a ritual drug and may have been known in India as “soma” around 2000 B.C.

EARLY ATTEMPTS AT GASTROINTESTINAL DECONTAMINATION

Nicander’s *Alexipharmaca* (Antidotes for Poisons) recommended induction of emesis by one of several methods: (a) ingesting warm linseed oil, (b) tickling the hypopharynx with a feather, or (c) “emptying the gullet with a small twisted and curved paper.”⁹² Nicander also advocated the use of suction to limit envenomation.¹⁴⁸ The Romans referred to the feather as the “vomiting feather” or “pinna.” Most commonly, the feather was used after a hearty feast to avoid the GI discomfort associated with overeating. At times, the pinna was dipped into a nauseating mixture to increase its efficacy.⁹⁵

TOXICOLOGY DURING THE MEDIEVAL AND RENAISSANCE PERIODS

After Galen (ca. A.D. 129–200), there is relatively little documented attention to the subject of poisons until the works of Ibn Wahshiya in the 9th century. Citing Greek, Persian, and Indian texts, Wahshiya’s work, titled *Book of Poisons*, combined contemporary science, magic, and astrology during his discussion of poison mechanisms (as they were understood at that time), symptomatology, antidotes (including his own recommendation for a universal antidote), and prophylaxis. He categorized poisons as lethal by sight, smell, touch, and sound, as well as by drinking and eating. For

victims of an aconite-containing dart arrow, Ibn Wahshiya recommended excision followed by cauterization and topical treatment with onion and salt.⁸⁷

Another significant medieval contribution to toxicology can be found in Moses Maimonides’ (1135–1204) *Treatise on Poisons and Their Antidotes* (1198). In part one of this treatise, Maimonides discussed the bites of snakes and mad dogs and the stings of bees, wasps, spiders, and scorpions.¹³¹ He also discussed the use of cupping glasses for bites (a progenitor of the modern suctioning device) and was one of the first to differentiate the hematotoxic (hot) from the neurotoxic (cold) effects of poison. In part two, he discussed mineral and vegetable poisons and their antidotes. He described belladonna poisoning as causing a “redness and a sort of excitation.”¹³¹ He suggested that emesis should be induced by hot water, *Anethum graveolens* (dill), and oil followed by fresh milk, butter, and honey. Although he rejected some of the popular treatments of the day, he advocated the use of the great theriac and the mithradatum as first- and second-line xenobiotics in the management of snakebite.¹³¹

On the subject of oleander poisoning, Petrus Abbonus (1250–1315) wrote that those who drink the juice, spines, or bark of oleander will develop anxiety, palpitations, and syncope.²² He described the clinical presentation of opium overdose as someone who “will be dull, lazy, and sleepy, without feeling, and he will neither understand nor feel anything, and if he does not receive succor, he will die.” Although this “succor” is not defined, he recommended that treatment of opium intoxication include drinking the strongest wine, rubbing the extremities with alkali and soap, and olfactory stimulation with pepper. To treat snakebite, Abbonus suggested the immediate application of a tourniquet, as well as oral suctioning of the bite wound, preferably performed by a servant. Interesting from a 21st-century perspective, Abbonus also suggested that St. John’s wort had the magical power to free anything from poisons and attributed this virtue to the influence of the stars.²²

The Scientists

Paracelsus’ (1493–1541) study on the dose–response relationship is usually considered the beginning of the scientific approach to toxicology (Table 1–2). He was the first to emphasize the chemical nature of toxic xenobiotics.¹¹⁷ Paracelsus stressed the need for proper observation and experimentation regarding the true response to xenobiotics. He underscored the need to differentiate between the therapeutic and toxic properties of chemicals when he stated in his Third Defense, “What is there that is not poison? All things are poison and nothing [is] without poison. Solely, the dose determines that a thing is not a poison.”⁴³

TABLE 1–2. Important Contributors to Toxicology

<i>Person</i>	<i>Date</i>	<i>Importance</i>
Paracelsus	1493–1541	Introduced the dose–response concept to toxicology
Ambroise Pare	1510–1590	Spoke out against unicorn horns and bezoars as antidotes
William Piso	1611–1678	First to study emetic qualities of ipecacuanha
Bernardino Ramazzini	1633–1714	Father of occupational medicine; wrote <i>De Morbis Artificum Diatriba</i>
Richard Mead	1673–1754	Wrote English-language book about poisoning
Percivall Pott	1714–1788	Wrote the first description of occupational cancer, relating the chimney sweep occupation to scrotal cancer
Felice Fontana	1730–1805	First scientific study of venomous snakes
Philip Physick	1767–1837	Early advocate of orogastric lavage to remove poisons
Baron Guillaume Dupuytren	1777–1835	Early advocate of orogastric lavage to remove poisons
Francois Magendie	1783–1855	Discovered emetine and studied the mechanisms of cyanide and strychnine
Bonaventure Orfila	1787–1853	Father of modern toxicology; wrote <i>Traite des Poisons</i> ; first to isolate arsenic from humans organs
James Marsh	1794–1846	Developed reduction test for arsenic
Robert Christison	1797–1882	Wrote <i>Treatise on Poisons</i> , one of the most influential texts of the early 19th century
Grand Marshall Bertrand	1813	Demonstrated the efficacy of activated charcoal in arsenic ingestion

Claude Bernard	1813–1878	Studied the mechanisms of toxicity of carbon monoxide and curare
Edward Jukes	1820	Self-experimented with orogastric lavage apparatus known as Jukes' syringe
Theodore Wormley	1826–1897	Wrote <i>Micro-Chemistry of Poisons</i> , the first American book devoted exclusively to toxicology
Pierre Touery	1831	Demonstrated the efficacy of activated charcoal in strychnine ingestion
Hugo Reinsch	1842–1884	Developed qualitative tests for arsenic and mercury
Alfred Garrod	1846	Conducted the first systematic study of activated charcoal in an animal model
Max Gutzeit	1847–1915	Developed method to quantitate small amounts of arsenic
Benjamin Howard Rand	1848	Conducted the first study of the efficacy of activated charcoal in humans
O.H. Costill	1848	Wrote the first book on symptoms and treatment of poisoning
Louis Lewin	1850–1929	Studied many toxins, including methanol, chloroform, snake venom, carbon monoxide, lead, opioids, and hallucinogenic plants
Rudolf Kobert	1854–1918	Studied digitalis and ergot alkaloids
Albert Niemann	1860	Isolated cocaine alkaloid
Alice Hamilton	1869–1970	Conducted landmark investigations associating worksite chemical hazards with disease; led reform movement to improve worker safety

Although Paracelsus is the best known Renaissance toxicologist, Ambroise Pare (1510–1590) and William Piso (1611–1678) also contributed to the field. Pare argued against the use of the unicorn horn and bezoar stone.⁹⁴ He also wrote an early treatise on carbon monoxide poisoning. Piso is credited as one of the first to recognize the emetic properties of ipecacuanha.¹²⁸

Medieval and Renaissance Poisoners

Along with these advances in toxicologic knowledge, the Renaissance is mainly remembered as the age of the poisoner, a time when the art of poisoning reached new heights (Table 1–3). In fact, poisoning was so rampant during this time that in 1531, King Henry VIII decreed that convicted poisoners should be boiled alive.⁵² From the 15th to 17th centuries, schools of poisoning existed in Venice and Rome. In Venice, poisoning services were provided by a group called the Council of Ten, whose members were hired to perform murder by poison.¹⁵⁵

TABLE 1–3. Notable Poisoners from Antiquity to the Present

<i>Poisoner</i>	<i>Date</i>	<i>Victim(s)</i>	<i>Poison(s)</i>
Locusta	54–55 A.D.	Claudius and Britannicus	<i>Amanita phalloides</i> , cyanide
Cesare Borgia	1400s	Cardinals and kings	La Cantarella (arsenic and phosphorus)
Catherine de Medici	1519–1589	Poor, sick, criminals	Unknown
Hieronyma Spara	Died 1659	Taught women how to poison their husbands	Mana of St. Nicholas of Bari (arsenic trioxide)
Marchioness de Brinvilliers	Died 1676	Hospitalized patients, husband, father	Antimony, arsenic, copper, lead, mercury
Catherine Deshayes	Died 1680	>2000 infants, many husbands	La poudre de succession (arsenic mixed with aconite, belladonna, and opium)
Madame Giulia Toffana	Died 1719	>600 people	Agua toffana (arsenic trioxide)
Mary Blandy	1752	Father	Arsenic
Anna Maria Zvanizer	1807	Random people	Antimony, arsenic
Marie Lefarge	1839	Husband	Arsenic (first use of Marsh test)
John Tawell	1845	Mistress	Cyanide
William Palmer, MD	1855	Fellow gambler	Strychnine
Madeline Smith (acquitted)	1857	Lover	Arsenic
Edmond de la Pommerai, MD	1863	Patient and mistress	Digitalis
Edward William Pritchard, MD	1865	Wife and mother-in-law	Antimony
George Henry Lamson, MD	1881	Brother-in-law	Aconite
Adelaide Bartlett (acquitted)	1886	Husband	Chloroform
Florence Maybrick	1889	Husband	Arsenic
Thomas Neville Cream, MD	1891	Prostitutes	Strychnine
Johann Hoch	1892–1905	Serial wives	Arsenic
Cordelia Botkin	1898	Rival woman	Arsenic (in chocolate candy)
Roland Molineux	1898	Acquaintance	Cyanide of mercury
Hawley Harvey Crippen, MD	1910	Wife	Hyoscine

Frederick Henry Seddon	1911	Boarder	Arsenic (fly paper)
Henri Girard Landru	1912	Acquaintances	<i>Amanita phalloides</i>
Robert Armstrong	1921	Wife	Arsenic (weed killer)
Landru	1922	Many women	Cyanide

Suzanne Fazekas	1929	Supplied poison to 100 wives to kill husbands	Arsenic
Sadamichi Hirasawa	1948	Bank employees	Potassium cyanide
Christa Ambros-Lehmaen	1954	Friend, husband, father-in-law	E-605 (parathion)
Nannie Doss	1954	11 relatives, including five husbands	Arsenic
Carl Coppolino, MD	1965	Wife	Succinylcholine
Graham Frederick Young	1971	Stepmother, coworkers	Antimony, thallium
Judas V. Buonoano	1971	Husband, son	Arsenic
Ronald Clark O'Bryan	1974	Son and neighborhood children	Cyanide (in Halloween candy)
Governmental	1978	Georgi Markov, Bulgarian dissident	Ricin
Jim Jones	1978	>900 people in mass suicide	Cyanide
Harold Shipman, MD	1974–1998	>100 patients	Heroin
Unidentified	1982	Seven random people	Extra Strength Tylenol mixed with cyanide
Donald Harvey	1983–1987	Patients	Arsenic
George Trepal	1988	Neighbors	Thallium
Michael Swango, MD	1980s–1990s	Hospitalized patients	Arsenic, potassium chloride, succinylcholine
Charles Cullen, RN	1990s–2003	Hospitalized patients	Digoxin
Governmental	2004	Viktor Yushchenko, Ukrainian presidential candidate	Dioxin
Governmental	2006	Alexander Litvinenko	Polonium-210

Members of the infamous Borgia family were considered to be responsible for many poisonings during this period. They preferred to use a poison called “La Cantarella,” a mixture of arsenic and phosphorus.¹⁴⁹ Rodrigo Borgia (1431–1503), who became Pope Alexander VI, and his son, Cesare Borgia, were reportedly responsible for the poisoning of cardinals and kings.

In the late 16th century, Catherine de Medici, wife of Henry II of France, introduced Italian poisoning techniques to France. She experimented on the poor, the sick, and the criminal. By analyzing the subsequent complaints of her victims, she is said to have learned the site of action and time of onset, the clinical signs and symptoms, and the efficacy of poisons.⁵⁶

Murder by poison remained quite popular during the latter half of the 17th and the early part of the 18th centuries in Italy and France.

The Marchioness de Brinvilliers (1630–1676) tested her poison concoctions on hospitalized patients and on her servants and allegedly murdered her husband, father, and two siblings.^{54,139} Among the favorite poisons of the Marchioness were arsenic, copper sulfate, corrosive sublimate (mercury bichloride), lead, and tartar emetic (antimony potassium tartrate).¹⁴⁹ Catherine Deshayes (1640–1680), a fortuneteller and sorceress, was one of the last “poisoners for hire” and was implicated in countless poisonings, including the killing of more than 2000 infants.⁵⁶ Better known as “La Voisine,” she reportedly sold poisons to women wishing to rid themselves of their husbands. Her particular brand of poison was a concoction of aconite, arsenic, belladonna, and opium known as la poudre de succession.¹⁴⁹ Ultimately, de Brinvilliers was beheaded and Deshayes was burned alive for their crimes. In an attempt to curtail these rampant poisonings, Louis XIV issued a decree in 1662 banning the sale of arsenic, mercury, and other poisons to customers not known to apothecaries and requiring buyers to sign a register declaring the purpose for their purchase.¹³⁹

A major center for poison practitioners was Naples, the home of the notorious Madame Giulia Toffana. She reportedly poisoned more than 600 people, preferring a particular solution of white arsenic (arsenic trioxide), better known as “aqua toffana,” and dispensed under the guise of a cosmetic. Eventually convicted of poisoning, Madame Toffana was executed in 1719.²¹

EIGHTEENTH-AND NINETEENTH-CENTURY DEVELOPMENTS IN

TOXICOLOGY

The development of toxicology as a distinct specialty began during the 18th and 19th centuries (Table 1–2).¹¹⁸ The mythological and magical mystique of poisoners began to be gradually replaced by an increasingly rational, scientific, and experimental approach to these agents. Much of the poison lore that had survived for almost 2000 years was finally debunked and discarded. The 18th-century Italian Felice Fontana was one of the first to usher in the modern age. He was an early experimental toxicologist who studied the venom of the European viper and wrote the classic text *Traite sur le Venin de la Vipere* in 1781.⁷⁹ Through his exacting experimental study on the effects of venom, Fontana brought a scientific insight to toxicology previously lacking and demonstrated that clinical symptoms resulted from the poison (venom) acting on specific target organs. During the 18th and 19th centuries, attention focused on the detection of poisons and the study of toxic effects of xenobiotics in animals.¹¹¹ Issues relating to adverse effects of industrialization and unintentional poisoning in the workplace and home environment were raised. Also during this time, early experience and experimentation with methods of GI decontamination took place.

Development of Analytical Toxicology and the Study of Poisons

The French physician Bonaventure Orfila (1787–1853) is often called the father of modern toxicology.¹¹¹ He emphasized toxicology as a distinct, scientific discipline, separate from clinical medicine and pharmacology.¹¹ He was also an early medical-legal expert who championed the use of chemical analysis and autopsy material as evidence to prove that a poisoning had occurred. His treatise *Traite des Poisons* (1814)¹¹⁶ evolved over five editions and was regarded as the foundation of experimental and forensic toxicology.¹⁵⁴ This text classified poisons into six groups: acrids, astringents, corrosives, narcoticoacrids, septic and putrefiants, and stupeficients and narcotics.

A number of other landmark works on poisoning also appeared during this period. In 1829, Robert Christison (1797–1882), a professor of medical jurisprudence and Orfila's student, wrote *A Treatise on Poisons*.³² This work simplified Orfila's poison classification schema by categorizing poisons into three groups: irritants, narcotics, and narcoticoacrids. Less concerned with jurisprudence than with clinical toxicology, O.H. Costill's *A Practical Treatise on Poisons*, published in 1848, was the first modern clinically oriented text to emphasize the symptoms and treatment of poisoning.³⁶ In 1867, Theodore Wormley (1826–1897) published the first American book written exclusively on poisons titled *Micro-Chemistry of Poisons*.^{48,157}

During this time, important breakthroughs in the chemical analysis of poisons resulted from the search for a more reliable assay for arsenic. Arsenic was widely available and was the suspected cause of a large number of deaths. In one study, arsenic was used in 31% of 679 homicidal poisonings.¹⁴⁹ A reliable means of detecting arsenic was much needed by the courts.

Until the 19th century, poisoning was mainly diagnosed by its resultant symptoms rather than by analytic tests. The first use of a chemical test as evidence in a poisoning trial occurred in the 1752 trial of Mary Blandy, who was accused of poisoning her father with arsenic.⁹⁹ Although Blandy was convicted and hanged publicly, the test used in this case was not very sensitive and depended in part on eliciting a garlic odor upon heating the gruel that the accused had fed to her father.

During the 19th century, James Marsh (1794–1846), Hugo Reinsch (1842–1884), and Max Gutzeit (1847–1915) each worked on this problem. Assays bearing their names are important contributions to the early history of analytic toxicology.^{100,111} The “Marsh test” to detect arsenic was first used in a criminal case in 1839 during the trial of Marie Lefarge, who was accused of using arsenic to murder her husband.¹³⁹ Orfila's trial testimony that the victim's viscera contained minute amounts of arsenic helped to convict the defendant, although subsequent debate suggested that contamination of the forensic specimen may have also played a role.

In a further attempt to curtail criminal poisoning by arsenic, the British Parliament passed the Arsenic Act in 1851. This bill, which was one of the first modern laws to regulate the sale of poisons, required that the retail sale of arsenic be restricted to chemists, druggists, and apothecaries and that a poison book be maintained to record all arsenic sales.¹⁵

Homicidal poisonings remained common during the 19th century and early 20th century. Infamous poisoners of that time included William Palmer, Edward Pritchard, Harvey Crippen, and Frederick Seddon.¹⁴⁹ Many of these poisoners were physicians who used their knowledge of medicine and toxicology in an attempt to solve their domestic and financial difficulties by committing the “perfect” murder. Some of the poisons used were aconitine (by Lamson, who was a classmate of Christison), *Amanita phalloides* (by Girard), arsenic (by Maybrick, Seddon, and others), antimony (by Pritchard), cyanide (by Molineux and Tawell), digitalis (by Pommerais), hyoscine (by Crippen), and strychnine (by Palmer and Cream) (Table 1–3).^{24,86,147,149}

In the early 20th century, forensic investigation into suspicious deaths, including poisonings, was significantly advanced with the development of the medical examiner system replacing the much-flawed coroner system that was subject to widespread corruption. In 1918, the first centrally controlled medical examiner system was established in New York City. Alexander Gettler, considered the father of forensic toxicology in the United States, established a toxicology laboratory

within the newly created New York City Medical Examiner's Office. Gettler pioneered new techniques for the detection of a variety of substances in biologic fluids, including carbon monoxide, chloroform, cyanide, and heavy metals.^{49,111}

Systematic investigation into the underlying mechanisms of toxic substances also commenced during the 19th century. Francois Magendie (1783–1855) studied the mechanisms of toxicity and sites of action of cyanide, emetine, and strychnine.⁴⁷ Claude Bernard (1813–1878), a pioneering physiologist and a student of Magendie, made important contributions to the understanding of the toxicity of carbon monoxide and curare.⁸⁵ Rudolf Kobert (1854–1918) studied digitalis and ergot alkaloids and authored a textbook on toxicology for physicians and students.^{83,114} Louis Lewin (1850–1929) was the first person to intensively study the differences between the pharmacologic and toxicologic actions of xenobiotics. Lewin studied chronic opium intoxication, as well as the toxicity of carbon monoxide, chloroform, lead, methanol, and snake venom. He also developed a classification system for psychoactive drugs, dividing them into euphorics, phantastics, inebriants, hypnotics, and excitants.⁹³

The Origin of Occupational Toxicology

The origins of occupational toxicology can be traced to the early 18th century and to the contributions of Bernardino Ramazzini (1633–1714). Considered the father of occupational medicine, Ramazzini wrote *De Morbis Artificum Diatriba* (Diseases of Workers) in 1700, which was the first comprehensive text discussing the relationship between disease and workplace hazards.⁵³ Ramazzini's essential contribution to patient care is epitomized by the addition of a standard question to a patient's medical history: "What occupation does the patient follow?"⁵¹ Altogether Ramazzini described diseases associated with 54 occupations, including hydrocarbon poisoning in painters, mercury poisoning in mirror makers, and pulmonary diseases in miners.

In 1775, Sir Percivall Pott proposed the first association between workplace exposure and cancer when he noticed a high incidence of scrotal cancer in English chimney sweeps. Pott's belief that the scrotal cancer was caused by prolonged exposure to tar and soot was confirmed by further investigation in the 1920s, indicating the carcinogenic nature of the polycyclic aromatic hydrocarbons contained in coal tar (including benzo[a]pyrene).⁷²

Dr. Alice Hamilton (1869–1970) was another pioneer in occupational toxicology whose rigorous scientific inquiry had a profound impact on linking chemical xenobiotics with human disease. A physician, scientist, humanitarian, and social reformer, Hamilton became the first female professor at Harvard University and conducted groundbreaking studies of many different occupational exposures and problems, including carbon monoxide poisoning in steelworkers, mercury poisoning in hatters, and wrist drop in lead workers. Hamilton's overriding concerns about these "dangerous trades" and her commitment to improving the health of workers led to extensive voluntary and regulatory reforms in the workplace.^{60,65}

Advances in Gastrointestinal Decontamination

Using gastric lavage and activated charcoal to treat poisoned patients was introduced in the late 18th and early 19th century. A stomach pump was first designed by Munro Secundus in 1769 to administer neutralizing substances to sheep and cattle for the treatment of bloat.²⁴ The American surgeon Philip Physick (1768–1837) and the French surgeon Baron Guillaume Dupuytren (1777–1835) were two of the first physicians to advocate gastric lavage for the removal of poisons.²⁵ As early as 1805, Physick demonstrated the use of a "stomach tube" for this purpose. Using brandy and water as the irrigation fluid, he performed stomach washings in twins to wash out excessive doses of tincture of opium.²⁵ Dupuytren performed gastric emptying by first introducing warm water into the stomach via a large syringe attached to a long flexible sound and then withdrawing the "same water charged with poison."²⁵ Edward Jukes, a British surgeon, was another early advocate of poison removal by gastric lavage. Jukes first experimented on animals, performing gastric lavage after the oral administration of tincture of opium. Attempting to gain human experience, he experimented on himself, by first ingesting 10 drams (600 g) of tincture of opium and then performing gastric lavage using a 25-inch-long, 0.5-inch-diameter tube, which became known as Jukes' syringe.¹⁰⁵ Other than some nausea and a 3-hour sleep, he suffered no ill effects, and the experiment was deemed a success.

The principle of using activated charcoal to adsorb xenobiotics was first described by Scheele (1773) and Lowitz (1785), but the medicinal use of activated charcoal dates to ancient times.³⁵ The earliest reference to the medicinal uses of activated charcoal is found in Egyptian papyrus from about 1500 B.C.³⁵ The activated charcoal used during Greek and Roman times, referred to as "wood charcoal," was used to treat those with anthrax, chlorosis, epilepsy, and vertigo. By the late 18th century, topical application of activated charcoal was recommended for gangrenous skin ulcers, and internal use of an activated charcoal-water suspension was recommended for use as a mouthwash and in the treatment of bilious conditions.³⁵

The first hint that activated charcoal might have a role in the treatment of poisoning came from a series of courageous self-experiments in France during the early 19th century. In 1813, the French chemist Bertrand publicly demonstrated the antidotal properties of activated charcoal by surviving a 5 g ingestion of arsenic trioxide that had been mixed with

activated charcoal.⁶⁸ Eighteen years later, before the French Academy of Medicine, the pharmacist Touery survived an ingestion consisting of 10 times the lethal dose of strychnine mixed with 15 g of activated charcoal.⁶⁸ One of the first reports of activated charcoal used in a poisoned patient was in 1834 by the American Hort, who successfully treated a mercury bichloride–poisoned patient with large amounts of powdered activated charcoal.³

In the 1840s, Garrod performed the first controlled study of activated charcoal when he examined its utility on a variety of poisons in animal models.⁶⁸ Garrod used dogs, cats, guinea pigs, and rabbits to demonstrate the potential benefits of activated charcoal in the management of strychnine poisoning. He also emphasized the importance of early use of activated charcoal and the proper ratio of activated charcoal to poison. Other toxic substances, such as aconite, hemlock, mercury bichloride, and morphine, were also studied during this period. The first activated charcoal efficacy studies in humans were performed by the American physician B. Rand in 1848.⁶⁸

But it was not until the early 20th century that an activation process was added to the manufacture of activated charcoal to increase its effectiveness. In 1900, the Russian Ostrejko demonstrated that treating activated charcoal with superheated steam significantly enhanced its adsorbing power.³⁵ Despite this improvement and the favorable reports mentioned, activated charcoal was only occasionally used in GI decontamination until the early 1960s, when Holt and Holz repopularized its use.⁶³

The Increasing Recognition of the Perils of Drug Abuse

Opioids. Although the medical use of opium was promoted by Paracelsus in the 16th century, the popularity of this agent was given a significant boost when the distinguished British physician Thomas Sydenham (1624–1689) formulated laudanum, which was a tincture of opium containing cinnamon, cloves, saffron, and sherry. Sydenham also formulated a different opium concoction known as “syrup of poppies.”⁸² A third opium preparation called Dover’s powder was designed by Sydenham’s protégé, Thomas Dover; this preparation contained syrup of ipecac, licorice, opium, salt-peter, and tartaric acid.

John Jones, the author of the 18th century text *The Mysteries of Opium Revealed*, was another enthusiastic advocate of its “medicinal” uses.⁸² A well-known opium user himself, Jones provided one of the earliest descriptions of opioid addiction. He insisted that opium offered many benefits if the dose was moderate but that discontinuation or a decrease in dose, particularly after “leaving off after long and lavish use,” would result in such symptoms as sweating, itching, diarrhea, and melancholy. His recommendation for the treatment of these withdrawal symptoms included decreasing the dose of opium by 1% each day until the drug was totally withdrawn. During this period, the number of English writers who became well-known opium addicts included Elizabeth Barrett Browning, Samuel Taylor Coleridge, and Thomas De Quincey. De Quincey, author of *Confessions of an English Opium Eater*, was an early advocate of the recreational use of opiates. The famed Coleridge poem *Kubla Khan* referred to opium as the “milk of paradise,” and De Quincey’s *Confessions* suggested that opium held the “key to paradise.” In many of these cases, the initiation of opium use for medical reasons led to recreational use, tolerance, and dependence.⁸²

Although opium was first introduced to Asian societies by Arab physicians some time after the fall of the Roman Empire, the use of opium in Asian countries grew considerably during the 18th and 19th centuries. China’s growing dependence on opium was spurred on by the English desire to establish and profit from a flourishing drug trade.¹³³ Opium was grown in India and exported east. Despite Chinese protests and edicts against this practice, the importation of opium persisted throughout the 19th century, with the British going to war twice in order to maintain their right to sell opium. Not surprisingly, by the beginning of the 20th century, opium abuse in China was endemic.

In England, opium use continued to increase during the first half of the 19th century. During this period, opium was legal and freely available from the neighborhood grocer. To many, its use was considered no more problematic than alcohol use.⁵⁸ The Chinese usually self-administered opium by smoking, a custom that was brought to the United States by Chinese immigrants in the mid-19th century; the English use of opium was more often by ingestion, that is, “opium eating.”

The liberal use of opioids as infant-soothing agents was one of the most unfortunate aspects of this period of unregulated opioid use.⁸³ Godfrey’s Cordial, Mother’s Friend, Mrs. Winslow’s Soothing Syrup, and Quietness were among the most popular opioids for children.⁸⁸ They were advertised as producing a natural sleep and recommended for teething and bowel regulation, as well as for crying. Because of the wide availability of opioids during this period, the number of acute opioid overdoses in children was consequential and would remain problematic until these unsavory remedies were condemned and removed from the market.

With the discovery of morphine in 1805 and Alexander Wood’s invention of the hypodermic syringe in 1853, parenteral administration of morphine became the preferred route of opioid administration for therapeutic use and abuse.⁷⁰ A legacy of the generous use of opium and morphine during the United States Civil War was “soldiers’ disease,” referring to a rather large veteran population that returned from the war with a lingering opioid habit.¹²⁵ One hundred years later, opioid abuse and addiction would again become common among the US military serving during the Vietnam War. Surveys indicated that as many as 20% of American soldiers in Vietnam were addicted to opioids during the war, partly because of its

widespread availability and high purity there.¹³⁰

Growing concerns about opioid abuse in England led to the passing of the Pharmacy Act of 1868, which restricted the sale of opium to registered chemists. But in 1898, the Bayer Pharmaceutical Company of Germany synthesized heroin from opium (Bayer also introduced aspirin that same year).¹⁴⁰ Although initially touted as a nonaddictive morphine substitute, problems with heroin use quickly became evident in the United States. Illicit heroin use reached epidemic proportions after World War II and again in the late 1960s.⁷¹ Although heroin use appeared to have leveled off by the end of the 20th century, an epidemic of prescription opioid abuse exploded during the first decade of the 21st century.⁹⁶

Cocaine. Ironically, during the later part of the 19th century, Sigmund Freud and Robert Christison, among others, promoted cocaine as a treatment for opiate addiction. After Albert Niemann's isolation of cocaine alkaloid from coca leaf in 1860, growing enthusiasm for cocaine as a panacea ensued.⁷⁸ Some of the most important medical figures of the time, including William Halsted, the famed Johns Hopkins surgeon, also extolled the virtues of cocaine use. Halsted championed the anesthetic properties of this drug, although his own use of cocaine and subsequent morphine use in an attempt to overcome his cocaine dependency would later take a considerable toll.¹¹⁵ In 1884, Freud wrote *Über Cocaine*,²⁷ advocating cocaine as a cure for opium and morphine addiction and as a treatment for fatigue and hysteria.

During the last third of the 19th century, cocaine was added to many popular nonprescription tonics. In 1863, Angelo Mariani, a Frenchman, introduced a new wine, "Vin Mariani," that consisted of a mixture of cocaine and wine (6 mg of cocaine alkaloid per ounce) and was sold as a digestive aid and restorative.¹⁰⁶ In direct competition with the French tonic was the American-made Coca-Cola, developed by J.S. Pemberton. It was originally formulated with coca and caffeine and marketed as a headache remedy and invigorator. With the public demand for cocaine increasing, patent medication manufacturers were adding cocaine to thousands of products. One such asthma remedy was "Dr. Tucker's Asthma Specific," which contained 420 mg of cocaine per ounce and was applied directly to the nasal mucosa.⁷⁸ By the end of the 19th century, the first American cocaine epidemic was underway.¹⁰⁸

Similar to the medical and societal adversities associated with opiate use, the increasing use of cocaine led to a growing concern about comparable adverse effects. In 1886, the first reports of cocaine-related cardiac arrest and stroke were published.¹²⁶ Reports of cocaine habituation occurring in patients using cocaine to treat their underlying opiate addiction also began to appear. In 1902, a popular book *Eight Years in Cocaine Hell* described some of these problems. *Century Magazine* called cocaine "the most harmful of all habit-forming drugs," and a report in *The New York Times* stated that cocaine was destroying "its victims more swiftly and surely than opium."⁴² In 1910, President William Taft proclaimed cocaine to be "public enemy number one."

In an attempt to curb the increasing problems associated with drug abuse and addiction, the 1914 Harrison Narcotics Act mandated stringent control over the sale and distribution of narcotics (defined as opium, opium derivatives, and cocaine).⁴² It was the first federal law in the United States to criminalize the nonmedical use of drugs. The bill required doctors, pharmacists, and others who prescribed narcotics to register and to pay a tax. A similar law, the Dangerous Drugs Act, was passed in the United Kingdom in 1920.⁵⁸ To help enforce these drug laws in the United States, the Narcotics Division of the Prohibition Unit of the Internal Revenue Service (a progenitor of the Drug Enforcement Agency) was established in 1920. In 1924, the Harrison Act was further strengthened with the passage of new legislation that banned the importation of opium for the purpose of manufacturing heroin, essentially outlawing the medicinal uses of heroin. With the legal venues to purchase these drugs now eliminated, users were forced to buy from illegal street dealers, creating a burgeoning black market that still exists today.

Sedative-Hypnotics. The introduction to medical practice of the anesthetic agents nitrous oxide, ether, and chloroform during the 19th century was accompanied by the recreational use of these agents and the first reports of volatile substance abuse. Chloroform "jags," ether "frolics," and nitrous parties became a new type of entertainment. Humphrey Davies was an early self-experimenter with the exhilarating effects associated with nitrous oxide inhalation. In certain Irish towns, especially where the temperance movement was strong, ether drinking became quite popular.¹⁰² Horace Wells, the American dentist who introduced chloroform as an anesthetic, became dependent on this volatile solvent and later committed suicide.

Until the last half of the 19th century, aconite, alcohol, hemlock, opium, and prussic acid (cyanide) were the primary agents used for sedation.³³ During the 1860s, new, more specific sedative-hypnotics, such as chloral hydrate and potassium bromide, were introduced into medical practice. In particular, chloral hydrate was hailed as a wonder drug that was relatively safe compared with opium and was recommended for insomnia, anxiety, and delirium tremens, as well as for scarlet fever, asthma, and cancer. But within a few years, problems with acute toxicity of chloral hydrate, as well as its potential to produce tolerance and physical dependence, became apparent.³³ Mixing chloral hydrate with ethanol, both of which inhibit each other's metabolism by competing with alcohol dehydrogenase, was noted to produce a rather powerful "knockout" combination that would become known as a "Mickey Finn" allegedly named after a Chicago saloon proprietor.¹⁶ Abuse of chloral hydrate, as well as other new sedatives such as potassium bromide, would prove to be a harbinger of 20th-century sedative-hypnotic abuse.

Absinthe, an ethanol-containing beverage that was manufactured with an extract from wormwood (*Artemisia absinthium*), was very popular during the last half of the 19th century.⁸⁴ This emerald-colored, very bitter drink was memorialized in the paintings of Degas, Toulouse-Lautrec, and Van Gogh and was a staple of French society during this period.¹² α -Thujone, a psychoactive component of wormwood and a noncompetitive γ -aminobutyric acid type A GABA_A blocker, is thought to be responsible for the pleasant feelings, hyperexcitability, and significant neurotoxicity associated with this drink.⁶⁷ Van Gogh’s debilitating episodes of psychosis were likely exacerbated by absinthe drinking.¹⁴⁴ Because of the medical problems associated with its use, absinthe was banned throughout most of Europe by the early 20th century.

Hallucinogens. Native Americans used peyote in religious ceremonies since at least the 17th century. Hallucinogenic mushrooms, particularly *Psilocybe* mushrooms, were also used in the religious life of Native Americans. These were called “teonanacatl,” which means “God’s sacred mushrooms” or “God’s flesh.”¹²¹ Interest in the recreational use of cannabis also accelerated during the 19th century after Napoleon’s troops brought the drug back from Egypt, where its use among the lower classes was widespread. In 1843, several French Romantics, including Balzac, Baudelaire, Gautier, and Hugo, formed a hashish club called “Le Club des Hachichins” in the Parisian apartment of a young French painter. Fitz Hugh Ludlow’s *The Hasheesh Eater*, published in 1857, was an early American text espousing the virtues of marijuana.⁹¹

A more recent event that had significant impact on modern-day hallucinogen use was the synthesis of lysergic acid diethylamide (LSD) by Albert Hofmann in 1938.⁶⁶ Working for Sandoz Pharmaceutical Company, Hofmann synthesized LSD while investigating the pharmacologic properties of ergot alkaloids. Subsequent self-experimentation by Hofmann led to the first description of its hallucinogenic effects and stimulated research into the therapeutic use of LSD. Hofmann is also credited with isolating psilocybin as the active ingredient in *Psilocybe mexicana* mushrooms in 1958.¹⁰⁶

TWENTIETH-CENTURY EVENTS

Early Regulatory Initiatives

The development of medical toxicology as a medical subspecialty and the important role of poison control centers began shortly after World War II. Before then, serious attention to the problem of household poisonings in the United States had been limited to a few federal legislative antipoisoning initiatives (Table 1–4). The 1906 Pure Food and Drug Act was the first federal legislation that sought to protect the public from problematic and potentially unsafe drugs and food. The driving force behind this reform was Harvey Wiley, the chief chemist at the Department of Agriculture. Beginning in the 1880s, Wiley investigated the problems of contaminated food. In 1902, he organized the “poison squad,” which consisted of a group of volunteers who did self-experiments with food preservatives.⁴ Revelations from the “poison squad,” as well as the publication of Upton Sinclair’s muckraking novel *The Jungle*¹³⁸ in 1906, exposed unhygienic practices of the meatpacking industry and led to growing support for legislative intervention. Samuel Hopkins Adams’ reports about the patent medicine industry revealed that some drug manufacturers added opiates to soothing syrups for infants and led to the call for reform.¹²⁷ Although the 1906 regulations were mostly concerned with protecting the public from adulterated food, regulations protecting against misbranded patent medications were also included.

TABLE 1–4. Protecting Our Health: Important US Regulatory Initiatives Pertaining to Xenobiotics

<i>Date</i>	<i>Federal Legislation</i>	<i>Intent</i>
1906	Pure Food and Drug Act	Early regulatory initiative. Prohibits interstate commerce of misbranded and adulterated foods and drugs.
1914	Harrison Narcotics Act	First federal law to criminalize the nonmedical use of drugs. Taxed and regulated distribution and sale of narcotics (opium, opium derivatives, and cocaine).
1927	Federal Caustic Poison Act	Mandated labeling of concentrated caustics.
1930	Food and Drug Administration (FDA)	Established successor to the Bureau of Chemistry; promulgation of food and drug regulations.
1937	Marijuana Tax Act	Applied controls to marijuana similar to those applied to narcotics.
1938	Federal Food, Drug, and Cosmetic Act	Required toxicity testing of pharmaceuticals before marketing.
1948	Federal Insecticide, Fungicide, and Rodenticide Act	Provided federal control for pesticide sale, distribution, and use.
1951	Durham-Humphrey Amendment	Restricted many therapeutic drugs to sale by prescription only.
1960	Federal Hazardous Substances Labeling Act	Mandated prominent labeling warnings on hazardous household chemical products.
1962	Kefauver-Harris Drug Amendments	Required drug manufacturers to demonstrate efficacy before marketing.
1963	Clean Air Act	Regulated air emissions by setting maximum pollutant standards.
1966	Child Protection Act	Banned hazardous toys when adequate label warnings could not be written.
1970	Comprehensive Drug Abuse and Control Act	Replaced and updated all previous laws concerning narcotics and other dangerous drugs.
1970	Environmental Protection Agency (EPA)	Established and enforced environmental protection standards.
1970	Occupational Safety and Health Act (OSHA)	Enacted to improve worker and workplace safety. Created National Institute for Occupational Safety and Health (NIOSH) as research institution for OSHA.
1970	Poison Prevention Packaging Act	Mandated child-resistant safety caps on certain pharmaceutical preparations to decrease unintentional childhood poisoning.
1972	Clean Water Act	Regulated discharge of pollutants into US waters.
1972	Consumer Product Safety Act	Established Consumer Product Safety Commission to reduce injuries and deaths from consumer products.

1972	Hazardous Material Transportation Act	Authorized the Department of Transportation to develop, promulgate, and enforce regulations for the safe transportation of hazardous materials.
1973	Drug Enforcement Administration (DEA)	Successor to the Bureau of Narcotics and Dangerous Drugs; charged with enforcing federal drug laws.
1973	Lead-based Paint Poison Prevention Act	Regulated the use of lead in residential paint. Lead in some paints was banned by Congress in 1978.

1974	Safe Drinking Water Act	Set safe standards for water purity.
1976	Resource Conservation and Recovery Act (RCRA)	Authorized EPA to control hazardous waste from the "cradle-to-grave," including the generation, transportation, treatment, storage, and disposal of hazardous waste.
1976	Toxic Substance Control Act	Emphasis on law enforcement. Authorized EPA to track 75,000 industrial chemicals produced or imported into the United States. Required testing of chemicals that pose environmental or human health risk.
1980	Comprehensive Environmental Response Compensation and Liability Act (CERCLA)	Set controls for hazardous waste sites. Established trust fund (Superfund) to provide cleanup for these sites. Agency for Toxic Substances and Disease Registry (ATSDR) created.
1983	Federal Anti-Tampering Act	Response to cyanide laced Tylenol deaths. Outlawed tampering with packaged consumer products.
1986	Controlled Substance Analogue Enforcement Act	Instituted legal controls on analog (designer) drugs with chemical structures similar to controlled substances.
1986	Drug-Free Federal Workplace Program	Executive order mandating drug testing of federal employees in sensitive positions.
1986	Superfund Amendments and Reauthorization Act (SARA)	Amendment to CERCLA. Increased funding for the research and cleanup of hazardous waste (SARA) sites.
1988	Labeling of Hazardous Art Materials Act	Required review of all art materials to determine hazard potential and mandated warning labels for hazardous materials.
1994	Dietary Supplement Health and Education Act	Permitted dietary supplements including many herbal preparations to bypass FDA scrutiny.
1997	FDA Modernization Act	Accelerated FDA reviews, regulated advertising of unapproved uses of approved drugs.
2002	The Public Health Security and Bioterrorism Preparedness and Response Act	Tightened control on biologic agents and toxins; increased safety of the US food and drug supply, and drinking water; and strengthened the Strategic National Stockpile.
2005	Combat Methamphetamine Epidemic Act	Part of the Patriot Act, this legislation restricted nonprescription sale of the methamphetamine precursor drugs ephedrine and pseudoephedrine used in the home production of methamphetamine.
2009	Family Smoking Prevention and Tobacco Control Act	Empowered FDA to set standards for tobacco products.

The Federal Caustic Poison Act of 1927 was the first federal legislation to specifically address household poisoning. As early as 1859, bottles clearly demarcated “poison” were manufactured in response to a rash of unfortunate dispensing errors that occurred when oxalic acid was unintentionally substituted for a similarly appearing Epsom salts solution.²⁸ Before 1927, however, “poison” warning labels were not required on chemical containers, regardless of toxicity or availability. The 1927 Caustic Act was spearheaded by the efforts of Chevalier Jackson, an otolaryngologist, who showed that unintentional exposures to household caustic agents were an increasingly frequent cause of severe oropharyngeal and GI burns. Under this statute, for the first time, alkali- and acid-containing products had to clearly display a “poison” warning label.¹⁴⁶

The most pivotal regulatory initiative the United States before World War II—and perhaps the most significant American toxicologic regulation of the 20th century—was the Federal Food, Drug, and Cosmetic Act of 1938. Although the Food and Drug Administration (FDA) had been established in 1930 and legislation to strengthen the 1906 Pure Food and Drug Act was considered by Congress in 1933, the proposed revisions still had not been passed by 1938. Then the elixir of sulfanilamide tragedy in 1938 ([Chap. 2](#)) claimed the lives of 105 people who had ingested a prescribed liquid preparation of the antibiotic sulfanilamide inappropriately dissolved in diethylene glycol. This event finally provided the catalyst for legislative intervention.^{104,153} Before the elixir disaster, proposed legislation called only for the banning of false and misleading drug labeling and for the outlawing of dangerous drugs without mandatory drug safety testing. After the tragedy, the proposal was strengthened to require assessment of drug safety before marketing, and the legislation was ultimately passed.

The Development of Poison Centers

World War II led to the rapid proliferation of new drugs and chemicals in the marketplace and in the household.³⁹ At the same time, suicide was recognized as a leading cause of death from these xenobiotics.⁹ Both of these factors led the medical community to develop a response to the serious problems of unintentional and intentional poisonings. In Europe during the late 1940s, special toxicology wards were organized in Copenhagen and Budapest,⁵⁹ and a poison information service was begun in the Netherlands ([Table 1–5](#)).¹⁵⁰ A 1952 American Academy of Pediatrics study revealed that more than 50% of childhood “accidents” in the United States were the result of unintentional poisonings.⁶¹ This study led Edward Press to open the first US poison center in Chicago in 1953.¹²² Press believed that it had become extremely difficult for

individual physicians to keep abreast of product information, toxicity, and treatment for the rapidly increasing number of potentially poisonous household products. His initial center was organized as a cooperative effort among the departments of pediatrics at several Chicago medical schools, with the goal of collecting and disseminating product information to inquiring physicians, mainly pediatricians.¹²⁴

TABLE 1–5. Milestones in the Development of Medical Toxicology in the United States

<i>Year</i>	<i>Milestone</i>
1952	American Academy of Pediatrics study shows that 51% of children's "accidents" are the result of the ingestion of potential poisons
1953	First US poison control center opens in Chicago
1957	National Clearinghouse for Poison Control Centers established
1958	American Association of Poison Control Centers (AAPCC) founded
1961	First Poison Prevention Week
1963	Initial call for development of regional Poison Control Centers (PCCs)
1964	Creation of European Association for PCCs
1968	American Academy of Clinical Toxicology (AACT) established
1972	Introduction of microfiche technology to poison information
1974	American Board of Medical Toxicology (ABMT) established
1978	AAPCC introduces standards of regional designation
1983	First examination given for Specialist in Poison Information (SPI)
1985	American Board of Applied Toxicology (ABAT) established
1992	Medical Toxicology recognized by American Board of Medical Specialties (ABMS)
1994	First ABMS examination in Medical Toxicology
2000	Accreditation Council for Graduate Medical Education (ACGME) approval of residency training programs in Medical Toxicology
2000	Poison Control Center Enhancement and Awareness Act
2004	Institute of Medicine (IOM) Report on the future of poison centers is released, calling for a greater integration between public health sector and poison control services

By 1957, 17 poison centers were operating in the United States.³⁹ With the Chicago center serving as a model, these early centers responded to physician callers by providing ingredient and toxicity information about drug and household products and making treatment recommendations. Records were kept of the calls, and preventive strategies were introduced into the community. As more poison centers opened, a second important function, providing information to calls from the general public, became increasingly common. The physician pioneers in poison prevention and poison treatment were predominantly pediatricians who focused on unintentional childhood ingestions.¹²⁹

During these early years in the development of poison centers, each center had to collect its own product information, which was a laborious and often redundant task.³⁸ In an effort to coordinate its operations and to avoid unnecessary duplication, Surgeon General James Goddard responded to the recommendation of the American Public Health Service and established the National Clearinghouse for Poison Control Centers in 1957.¹⁰¹ This organization, placed under the Bureau of Product Safety of the Food and Drug Administration, disseminated 5-inch by 8-inch index cards containing poison information to each center to help standardize poison center information resources. The Clearinghouse also collected and

tabulated poison data from each of the centers.

Between 1953 and 1972, a rapid, uncoordinated proliferation of poison centers occurred in the United States.⁹⁸ In 1962, there were 462 poison centers. By 1970, this number had risen to 590,⁸⁹ and by 1978, there were 661 poison centers in the United States, including 100 centers in the state of Illinois alone.¹³⁵ The nature of calls to centers changed as lay public-generated calls began to outnumber physician-generated calls. Recognizing the public relations value and strong popular support associated with poison centers, some hospitals started poison centers without adequately recognizing or providing for the associated responsibilities. Unfortunately, many of these centers offered no more than a part-time telephone service located in the back of the emergency department or pharmacy staffed by poorly trained personnel.¹³⁵

Despite the “growing pains” of these poison services during this period, many significant achievements were made. A dedicated group of physicians and other health care professionals began devoting an increasing proportion of their time to poison-related matters. In 1958, the American Association of Poison Control Centers (AAPCC) was founded to promote closer cooperation between poison centers, to establish uniform standards, and to develop educational programs for the general public and health care professionals.⁶¹ Annual research meetings were held, and important legislative initiatives were stimulated by the organization’s efforts.¹⁰¹ Examples of such legislation include the Federal Hazardous Substances Labeling Act of 1960, which improved product labeling; the Child Protection Act of 1966, which extended labeling statutes to pesticides and other hazardous substances; and the Poison Prevention Packaging Act of 1970, which mandated safety packaging. In 1961, in an attempt to heighten public awareness of the dangers of unintentional poisoning, the third week of March was designated as the Annual National Poison Prevention Week.

Another organization that would become important, the American Academy of Clinical Toxicology (AACT), was founded in 1968 by a diverse group of toxicologists.³⁴ This group was “interested in applying principles of rational toxicology to patient treatment” and in improving the standards of care on a national basis.¹³² The first modern textbooks of clinical toxicology began to appear in the mid-1950s with the publication of Dreisbach’s *Handbook of Poisoning* (1955)⁴⁵; Gleason, Gosselin, and Hodge’s *Clinical Toxicology of Commercial Products* (1957)⁵⁷; and Arena’s *Poisoning* (1963).¹⁰ Major advancements in the storage and retrieval of poison information were also instituted during these years. Information as noted above on consumer products initially appeared on index cards distributed regularly to poison centers by the National Clearinghouse, and by 1978, more than 16,000 individual product cards had been issued.¹³⁵ The introduction of microfiche technology in 1972 enabled the storage of much larger amounts of data in much smaller spaces at the individual poison centers. Toxifile and POISINDEX, two large drug and poison databases using microfiche technology, were introduced and gradually replaced the much more limited index card system.¹³⁵ During the 1980s, POISINDEX, which had become the standard database, was made more accessible by using CD-ROM technology. Sophisticated information about the most obscure xenobiotics was now instantaneously available by computer at every poison center.

In 1978, the poison center movement entered an important new stage in its development when the AAPCC introduced standards for regional poison center designation.⁹⁸ By defining strict criteria, the AAPCC sought to upgrade poison center operations significantly and to offer a national standard of service. These criteria included using poison specialists dedicated exclusively to operating the poison center 24 hours per day and serving a catchment area of between 1 and 10 million people. Not surprisingly, this professionalization of the poison center movement led to a rapid consolidation of services. An AAPCC credentialing examination for poison information specialists was inaugurated in 1983 to help ensure the quality and standards of poison center staff.⁷

In 2000, the Poison Control Center Enhancement and Awareness Act was passed by Congress and signed into law by President Clinton. For the first time, federal funding became available to provide assistance for poison prevention and to stabilize the funding of regional poison centers. This federal assistance permitted the establishment of a single nationwide toll-free phone number (800-222-1222) to access poison centers. At present, 57 centers contribute data to a National Poison Database System (NPDS) which from 1983 to 2006 was known as Toxic Exposure Surveillance System (TESS). Recently, the Centers for Disease Control and Prevention (CDC) has been collaborating with the AAPCC to conduct real-time surveillance of this data to help facilitate the early detection of chemical exposures of public health importance.¹⁵⁶

A poison center movement has also grown and evolved in Europe over the past 35 years, but unlike the movement in the United States, it focused from the beginning on establishing strong centralized toxicology treatment centers. In the late 1950s, Gaultier in Paris developed an inpatient unit dedicated to the care of poisoned patients.⁵⁹ In the United Kingdom, the National Poison Information Service developed at Guys Hospital in 1963 under Roy Goulding. Henry Matthew initiated a regional poisoning treatment center in Edinburgh about the same time.¹²⁴ In 1964, the European Association for Poison Control Centers was formed in Tours, France.⁵⁹

The Rise of Environmental Toxicology and Further Regulatory Protection from Toxic Substances

The rise of the environmental movement during the 1960s can be traced, in part, to the publication of Rachel Carson’s

Silent Spring in 1962, which revealed the perils of an increasingly toxic environment.²⁹ The movement also benefited from the new awareness by those involved with the poison movement of the growing menace of xenobiotics in the home environment.²⁶ Battery casing fume poisoning, resulting from the burning of discarded lead battery cases, and acrodynia, resulting from exposure to a variety of mercury-containing products,⁴¹ both demonstrated that young children are particularly vulnerable to low-dose exposures from certain xenobiotics. Worries about the persistence of pesticides in the ecosystem and the increasing number of chemicals introduced into the environment added to concerns of the environment as a potential source of illness, heralding a drive for additional regulatory protection.

Starting with the Clean Air Act in 1963, laws were passed to help reduce the toxic burden on our environment (Table 1–4). The establishment of the Environmental Protection Agency (EPA) in 1970 spearheaded this attempt at protecting our environment, and during the next 10 years, numerous protective regulations were introduced. Among the most important initiatives was the Occupational Safety and Health Act of 1970, which established the Occupational Safety and Health Administration (OSHA). This act mandates that employers provide safe work conditions for their employees. Specific exposure limits to toxic chemicals in the workplace were promulgated. The Consumer Product Safety Commission was created in 1972 to protect the public from consumer products that posed an unreasonable risk of illness or injury. Cancer-producing substances, such as asbestos, benzene, and vinyl chloride, were banned from consumer products as a result of these new regulations. Toxic waste disasters such as those at Love Canal, New York, and Times Beach, Missouri, led to the passing of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, also known as the Superfund) in 1980. This fund is designed to help pay for cleanup of hazardous substance releases posing a potential threat to public health. The Superfund legislation also led to the creation of the Agency for Toxic Substances and Disease Registry (ATSDR), a federal public health agency charged with determining the nature and extent of health problems at Superfund sites and advising the US EPA and state health and environmental agencies on the need for cleanup and other actions to protect the public's health. In 2003, the ATSDR became part of the National Center for Environmental Health of the CDC.

Medical Toxicology Comes of Age

Over the past 25 years, the primary specialties of medical toxicologists have changed. The development of emergency medicine and preventive medicine as medical specialties led to the training of more physicians with a dedicated interest in toxicology. By the early 1990s, emergency physicians accounted for more than half the number of practicing medical toxicologists. The increased diversity of medical toxicologists with primary training in emergency medicine, pediatrics, preventive medicine, or internal medicine has helped broaden the goals of poison centers and medical toxicologists beyond the treatment of acute unintentional childhood ingestions. The scope of medical toxicology now includes a much wider array of toxic exposures, including acute and chronic, adult and pediatric, unintentional and intentional, and occupational and environmental exposures.

The development of medical toxicology as a medical subspecialty began in 1974, when the AACT created the American Board of Medical Toxicology (ABMT) to recognize physician practitioners of medical toxicology.⁵ From 1974 to 1992, 209 physicians obtained board certification, and formal subspecialty recognition of medical toxicology by the American Board of Medical Specialties (ABMS) was granted in 1992. In that year, a conjoint subboard with representatives from the American Board of Emergency Medicine, American Board of Pediatrics, and American Board of Preventive Medicine was established, and the first ABMS-sanctioned examination in medical toxicology was offered in 1994. By 2013, a total of more than 450 physicians were board certified in medical toxicology. The American College of Medical Toxicology (ACMT) was founded in 1994 as a physician-based organization designed to advance clinical, educational, and research goals in medical toxicology. In 1999, the Accreditation Council of Graduate Medical Education (ACGME) in the United States formally recognized postgraduate education in medical toxicology, and by 2013, 29 fellowship training programs had been approved.

During the 1990s in the United States, some medical toxicologists began to work on establishing regional toxicology treatment centers. Adapting the European model, such toxicology treatment centers could serve as referral centers for patients requiring advanced toxicologic evaluation and treatment. Goals of such inpatient regional centers included enhancing care of poisoned patients, strengthening toxicology training, and facilitating research. The evaluation of the clinical efficacy and fiscal viability of such programs is ongoing.

The professional maturation of advanced practice pharmacists and nurses with primary interests in clinical toxicology has also taken place over the past 2 decades. In 1985, the AACT established the American Board of Applied Toxicology (ABAT) to administer certifying examinations for nonphysician practitioners of medical toxicology who meet their rigorous standards.⁴ By 2013, more than 85 toxicologists, who mostly held either a PharmD or a PhD in pharmacology or toxicology, were certified by this board.

Recent Poisonings and Poisoners

Although accounting for just a tiny fraction of all homicidal deaths (0.16% in the United States), notorious lethal poisonings

continued throughout the 20th century (Table 1–3).¹

In England, Graham Frederick Young developed a macabre fascination with poisons.³⁰ In 1971, at age 14 years, he killed his stepmother and other family members with arsenic and antimony. Sent away to a psychiatric hospital, he was released at age 24 years, when he was no longer considered to be a threat to society. Within months of his release, he again engaged in lethal poisonings, killing several of his coworkers with thallium. Ultimately, he died in prison in 1990.

In 1978, Georgi Markov, a Bulgarian defector living in London, developed multisystem failure and died 4 days after having been stabbed by an umbrella carried by an unknown assailant. The postmortem examination revealed a pinhead-sized metal sphere embedded in his thigh where he had been stabbed. Investigators hypothesized that this sphere had most likely carried a lethal dose of ricin into the victim.³⁷ This theory was greatly supported when ricin was isolated from the pellet of a second victim who was stabbed under similar circumstances.

In 1982, deliberate tampering of nonprescription Tylenol preparations with potassium cyanide caused seven deaths in Chicago.⁴⁶ Because of this tragedy, packaging of nonprescription medications was changed to decrease the possibility of future product tampering.¹⁰⁷ The perpetrator(s) were never apprehended, and other deaths from nonprescription product tampering were reported in 1991.³¹

In 1998, Judias Buenoano, known as the “black widow,” was executed for murdering her husband with arsenic in 1971 to collect insurance money. She was the first woman executed in Florida in 150 years. The fatal poisoning had remained undetected until 1983, when Buenoano was accused of trying to murder her fiancé with arsenic and by car bombing. Exhumation of the husband’s body, 12 years after he died, revealed substantial amounts of arsenic in the remains.²

Health care providers have been implicated in several poisoning homicides as well. An epidemic of mysterious cardiopulmonary arrests at the Ann Arbor Veterans Administration Hospital in Michigan in July and August 1975 was attributed to the homicidal use of pancuronium by two nurses.¹⁴⁵ Intentional digoxin poisoning by hospital personnel may have explained some of the increased number of deaths on a cardiology ward of a Toronto pediatric hospital in 1981, but the cause of the high mortality rate remained unclear.²³ In 2000, an English general practitioner Harold Shipman was convicted of murdering 15 women patients with heroin and may have murdered as many as 297 patients during his 24-year career. These recent revelations prompted calls for strengthening the death certification process, improving preservation of case records, and developing better procedures to monitor controlled drugs.⁶⁹

Also in 2000, Michael Swango, an American physician, pleaded guilty to the charge of poisoning a number of patients under his care during his residency training. Succinylcholine, potassium chloride, and arsenic were used to kill his patients.¹⁴³ Attention to more careful physician credentialing and to maintenance of a national physician database arose from this case because the poisonings occurred at multiple hospitals across the country. Continuing concerns about health care providers acting as serial killers is highlighted by a recent case in New Jersey in which a nurse, Charles Cullen, was found responsible for killing patients with digoxin.¹⁷

By the end of the 20th century, 24 centuries after Socrates was executed by poison hemlock, the means of implementing capital punishment had come full circle. Government-sanctioned execution in the United States again favored the use of a “state” poison—this time, the combination of sodium thiopental, pancuronium, and potassium chloride.

The use of a poison to achieve political ends has again resurfaced in several incidents from the former Soviet Union. In December 2004, it was announced that the Ukrainian presidential candidate Viktor Yushchenko was poisoned with 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), a potent dioxin.¹⁴¹ The dramatic development of chloracne over the face of this public person during the previous several months suggested dioxin as a possibly culprit. Given the paucity of reports of acute dioxin poisoning, however, it was not until laboratory tests confirmed that Yushenko’s dioxin concentrations were more than 6000 times normal that this diagnosis was confirmed. In another case, a former KGB agent and Russian dissident Alexander Litvinenko was murdered with polonium-210. Initially thought to be a possible case of heavy metal poisoning, Litvinenko developed acute radiation syndrome manifested by acute GI symptoms followed by alopecia and pancytopenia before he died.¹⁰³

Other Developments

Medical Errors. Beginning in the 1980s, several highly publicized medication errors received considerable public attention and provided a stimulus for the initiation of change in policies and systems. Ironically, all of the cases occurred at nationally preeminent university teaching hospitals. In 1984, 18 year-old Libby Zion died from severe hyperthermia soon after hospital admission. Although the cause of her death was likely multifactorial, drug–drug interactions and the failure to recognize and appropriately treat her agitated delirium also contributed to her death.¹³ State and national guidelines for closer house staff supervision, improved working conditions, and a heightened awareness of consequential drug–drug interactions resulted from the medical, legislative, and legal issues of this case. In 1994, a prominent health journalist for the Boston Globe, Betsy Lehman, was the unfortunate victim of another preventable dosing error when she inadvertently received four times the dose of the chemotherapeutic cyclophosphamide as part of an experimental protocol.⁸⁰ Despite treatment at a world-renowned cancer center, multiple physicians, nurses, and pharmacists failed to notice this erroneous

medication order. An overhaul of the medication-ordering system was implemented at that institution after this tragic event.

Another highly publicized death occurred in 1999 when 18-year-old Jesse Gelsinger died after enrolling in an experimental gene-therapy study. Gelsinger, who had ornithine transcarbamylase deficiency, died from multiorgan failure 4 days after receiving, by hepatic infusion, the first dose of an engineered adenovirus containing the normal gene. Although this unexpected death was not the direct result of a dosing or drug–drug interaction error, the FDA review concluded that major research violations had occurred, including failure to report adverse effects with this therapy in animals and earlier clinical trials and to properly obtain informed consent.¹³⁷ In 2001, Ellen Roche, a 24 year-old healthy volunteer in an asthma study at John Hopkins University, developed a progressive pulmonary illness and died one month after receiving 1 g of hexamethonium by inhalation as part of the study protocol.¹⁴² Hexamethonium, a ganglionic blocker, was once used to treat hypertension but was removed from the market in 1972. The investigators were cited for failing to indicate on the consent form that hexamethonium was experimental and not FDA approved. Calls for additional safeguards to protect patients in research studies resulted from these cases.

In late 1999, the problems of medical errors finally received the high visibility and deserved attention in the United States with the publication and subsequent reaction to an Institute of Medicine (IOM) report suggesting that 44,000 to 98,000 fatalities each year were the result of medical errors.⁸¹ Many of these errors were attributed to preventable medication errors. The IOM report focused on its findings that errors usually resulted from system faults and not solely from the carelessness of individuals.

Toxicology in the Twenty-First Century

As new challenges and opportunities arise in the 21st century, two new toxicologic disciplines have emerged: toxicogenomics and nanotoxicology.^{40,44,113} These nascent fields constitute the toxicologic responses to rapid advances in genetics and material sciences. Toxicogenomics combines toxicology with genomics dealing with how genes and proteins respond to toxic substances. The study of toxicogenomics attempts to better decipher the molecular events underlying toxicologic mechanisms, develop predictors of toxicity through the establishment of better molecular biomarkers, and better understand genetic susceptibilities that pertain to toxic substances such as unanticipated idiosyncratic drug reactions.

Nanotoxicology refers to the toxicology of engineered tiny particles, usually smaller than 100 nm. Given the extremely small size of nanoparticles, typical barriers at portals of entry may not prevent absorption or may themselves be adversely affected by the nanoparticles. Ongoing studies focus on the translocation of these particles to sensitive target sites such as the central nervous system or bone marrow (Chap. 129).¹¹³

SUMMARY

- Since the dawn of recorded history, toxicology has impacted greatly on human events and our ecosystem.
- Over the millennia, although the important poisons of the day have changed to some degree, toxic substances continue to challenge our safety.
- The era of poisoners for hire may have long ago reached its pinnacle, but problems with drug abuse, intentional self-poisoning, and exposure to environmental chemicals continue to challenge us.
- Knowledge acquired by one generation is often forgotten or discarded inappropriately by the next generation, leading to a cyclical historic course.

2 TOXICOLOGIC MISFORTUNES AND CATASTROPHES IN HISTORY

Paul M. Wax

Throughout history, mass poisonings have caused suffering and misfortune. From the ergot epidemics of the Middle Ages to contemporary industrial disasters, these mass events have had great political, economic, social, and environmental ramifications. Particularly within the past 100 years, as the number of toxins and potential toxins has risen dramatically, toxic disasters have become an increasingly common event. The sites of some of these events—Bhopal (India), Chernobyl (Ukraine), Jonestown (Guyana), Love Canal (New York), Minamata Bay (Japan), Seveso (Italy), West Bengal (India)—have come to symbolize our increasing potential for toxicity in our environment. Globalization has led to the proliferation of toxic chemicals throughout the world and their rapid distribution. Many chemical factories that store large amounts of potentially lethal chemicals are not secure. Given the increasing attention to terrorism preparedness, an appreciation of chemicals as agents of opportunity for terrorists has suddenly assumed great importance. This chapter provides an overview of some of the most consequential and historically important toxin-associated mass poisonings that represent human and environmental disasters.

GAS DISASTERS

Inhalation of toxic gases and oral ingestions resulting in food poisoning tend to subject the greatest number of people to adverse consequences of a toxic exposure. Toxic gas exposures may be the result of a natural disaster (volcanic eruption), industrial mishap (fire, chemical release), chemical warfare, or an intentional homicidal or genocidal endeavor (concentration camp gas chamber). Depending on the toxin, the clinical presentation may be acute, with a rapid onset of toxicity (cyanide), or subacute or chronic, with a gradual onset of toxicity (air pollution).

One of the earliest recorded toxic gas disasters resulted from the eruption of Mount Vesuvius near Pompeii, Italy, in 79 A.D. (Table 2–1). Poisonous gases generated from the volcanic activity reportedly killed thousands of people.³⁴ A much more recent natural disaster occurred in 1986 in Cameroon when excessive amounts of carbon dioxide spontaneously erupted from Lake Nyos, a volcanic crater lake.¹⁹ Approximately 1700 human and countless animal fatalities resulted from exposure to this asphyxiant.

TABLE 2–1. Gas Disasters

<i>Xenobiotic</i>	<i>Location</i>	<i>Date</i>	<i>Significance</i>
Poisonous gas	Pompeii, Italy	79 A.D.	>2000 deaths from eruption of Mt. Vesuvius
Smog (SO ₂)	London, England	1873	268 deaths from bronchitis
NO ₂ , CO, CN	Cleveland Clinic, Cleveland, OH	1929	Fire in radiology department; 125 deaths
Smog (SO ₂)	Meuse Valley, Belgium	1930	64 deaths
CO, CN	Cocoanut Grove Night Club, Boston	1942	498 deaths from fire
CO	Salerno, Italy	1944	>500 deaths on a train stalled in a tunnel
Smog (SO ₂)	Donora, PA	1948	20 deaths; thousands ill
Smog (SO ₂)	London, England	1952	4000 deaths attributed to the fog and smog
Dioxin	Seveso, Italy	1976	Unintentional industrial release of dioxin into environment; chloracne
Methyl isocyanate	Bhopal, India	1984	>2000 deaths; 200,000 injuries
Carbon dioxide	Cameroon, Africa	1986	>1700 deaths from release of gas from Lake Nyos
Hydrofluoric acid	Texas City, TX	1987	Atmospheric release; 94 hospitalized
CO, CN	Happy Land Social Club, Bronx, NY	1990	87 deaths in fire from toxic smoke
Hydrogen sulfide	Xiaoying, China	2003	243 deaths and 10,000 became ill from gas poisoning after a gas well exploded
CO, CN	West Warwick, RI	2003	98 deaths in fire

A toxic gas leak at the Union Carbide pesticide plant in Bhopal, India, in 1984 resulted in one of the greatest civilian toxic disasters in modern history.¹²⁹ An unintended exothermic reaction at this carbaryl-producing plant caused the release of more than 24,000 kg of methyl isocyanate. This gas was quickly dispersed through the air over the densely populated area surrounding the factory where many of the workers lived, resulting in at least 2500 deaths and 200,000 injuries.⁸⁰ The initial response to this disaster was greatly limited by a lack of pertinent information about the toxicity of this chemical as well as the poverty of the residents. A follow-up study 10 years later showed persistence of small airway obstructive disease among survivors as well as chronic eye problems.³⁰ Calls for improvement in disaster preparedness and strengthened “right-to-know” laws regarding potential toxic exposures resulted from this tragedy.^{48,129}

The release into the atmosphere of 26 tons of hydrofluoric acid at a petrochemical plant in Texas in October 1987 resulted in 939 people seeking medical attention at nearby hospitals. Ninety-four people were hospitalized, but there were no deaths.¹³⁷

More than any other single toxin, carbon monoxide has been involved in the largest number of toxic disasters. Catastrophic fires, such as the Cocoanut Grove Nightclub fire in 1943, have caused hundreds of deaths at a time, many of them from carbon monoxide poisoning.³⁶ A 1990 fire deliberately started at the Happy Land Social Club in the Bronx, New York, claimed 87 victims, including a large number of nonburn deaths,⁷² and the 2003 fire at the Station nightclub in West Warwick, Rhode Island, killed 98 people.¹¹⁵ Carbon monoxide poisoning was a major determinant in many of these deaths, although hydrogen cyanide gas and simple asphyxiation may have also contributed to the overall mortality.

Another notable toxic gas disaster involving a fire occurred at the Cleveland Clinic in Cleveland, Ohio, in 1929, where a fire in the radiology department resulted in 125 deaths.³³ The burning of nitrocellulose radiographs produced nitrogen

dioxide, cyanide, and carbon monoxide gases held responsible for many of the fatalities. In 2003, at least 243 people died and 10,000 became ill after a drilling well exploded in Gaogiao, China, releasing hydrogen sulfide and natural gas into the air.¹⁴² A toxic gas cloud covered 25 square kilometers. Ninety percent of the villagers who lived in the village adjoining the gas well died.

The release of a dioxin-containing chemical cloud into the atmosphere from an explosion at a hexachlorophene production factory in Seveso, Italy, in 1976 resulted in one of the most serious exposures to dioxin (2,3,7,8-tetrachlorodibenzo-p-dioxin).⁴⁷ The lethality of this xenobiotic in animals has caused considerable concern for acute and latent injury from human exposure. Despite this apprehension, chloracne was the only significant clinical finding related to the dioxin exposure at 5-year follow-up.⁹

Air pollution is another source of toxic gases that causes significant disease and death. Complaints about smoky air date back to at least 1272, when King Edward I banned the burning of sea coal.¹²⁷ By the 19th century, the era of rapid industrialization in England, winter “fogs” became increasingly problematic. An 1873 London fog was responsible for 268 deaths from bronchitis. Excessive smog in the Meuse Valley of Belgium in 1930 and in Donora, Pennsylvania, in 1948 was also blamed for excess morbidity and mortality. In 1952, another dense sulfur dioxide–laden smog in London was responsible for 4000 deaths.⁶⁹ Both the initiation of long-overdue air pollution reform in England and Parliament’s passing of the 1956 Clean Air Act resulted from this latter “fog.”

WARFARE AND TERRORISM

Exposure to xenobiotics with the deliberate intent to inflict harm claimed an extraordinary number of victims during the 20th century (Table 2–2). During World War I, chlorine, phosgene, and the liquid vesicant mustard were used as battlefield weapons, with mustard causing approximately 80% of the chemical casualties.¹¹⁷ Reportedly, 100,000 deaths and 1.2 million casualties were attributable to these chemical attacks.³⁴ The toxic exposures resulted in severe airway irritation, acute respiratory distress syndrome, hemorrhagic pneumonitis, skin blistering, and ocular damage. Chemical weapons were used again in the 1980s during the war between Iran and Iraq.

TABLE 2–2. Warfare and Terrorism Disasters

Toxin	Location	Date	Significance
Chlorine, mustard gas, phosgene	Ypres, Belgium	1915–1918	100,000 dead and 1.2 million casualties from chemicals during World War I
CN, CO	Europe	1939–1945	Millions murdered by Zyklon-B (HCN) gas
Agent Orange	Vietnam	1960s	Contains dioxin; excess skin cancer
Mustard gas	Iraq–Iran	1982	New cycle of war gas casualties
Possible toxin	Persian Gulf	1991	Gulf War syndrome
Sarin	Matsumoto, Japan	1994	First terrorist attack in Japan using sarin
Sarin	Tokyo, Japan	1995	Subway exposure; 5510 people sought medical attention
Dust and other particulates	New York, NY	2001	World Trade Center collapse from terrorist air strike
Fentanyl derivative	Moscow, Russia	2002	Used by the Russian military to subdue terrorists in Moscow theater
Ricin	Washington, DC	2004	Detected in Dirksen Senate Office Building; no illness reported
Chlorine	Iraq	2007	Used against US troops and Iraqi civilians

The Nazis used poisonous gases during World War II to commit mass murder. Initially, the Nazis used carbon monoxide to kill. To expedite the killing process, Nazi scientists developed Zyklon-B gas (hydrogen cyanide gas). As many as 10,000 people per day were killed by the rapidly acting cyanide, and millions of deaths were attributable to the use of these gases.

Agent Orange was widely used as a defoliant during the Vietnam War. This herbicide consisted of a mixture of 2,4,5-trichlorophenoxy-acetic acid (2,4,5-T) and 2,4-dichlorophenoxyacetic acid (2,4-D), as well as small amounts of a contaminant, 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), better known as dioxin. Over the years, a large number of adverse health effects have been attributed to Agent Orange exposure. A 2002 Institute of Medicine study concluded that among Vietnam veterans, there is sufficient evidence to demonstrate an association between this herbicide exposure and

chronic lymphocytic leukemia, soft tissue sarcomas, non-Hodgkin lymphomas, Hodgkin disease, and chloracne.⁵³

Mass exposure to the very potent organic phosphorus compound sarin occurred in March 1995 when terrorists released this chemical warfare agent in three separate Tokyo subway lines.⁹⁶ Eleven people were killed, and 5510 people sought emergency medical evaluation at more than 200 hospitals and clinics in the area.¹¹⁸ This calamity introduced the spectra of terrorism to the modern emergency medical services system, resulting in a greater emphasis on hospital preparedness, including planning for the psychological consequences of such events. Sarin exposure also resulted in several deaths and hundreds of casualties in Matsumoto, Japan, in June 1994.^{85,93}

After the terrorist attacks on New York City on September 11, 2001, that resulted in the collapse of World Trade Center, persistent cough and increased bronchial responsiveness were noted among 8% of New York City Fire Department workers who were exposed to large amounts of dust and other particulates during the clean-up.^{102,103} This condition, known as World Trade Center cough syndrome, is characterized by upper airway (chronic rhinosinusitis) and lower airway findings (bronchitis, asthma, or both) as well as, at times, gastroesophageal reflux dysfunction. The risk of development of hyperreactivity and reactive airways dysfunction was clearly associated with the intensity of exposure.¹⁶ A World Trade Center health registry has been established to investigate if those exposed workers may be at increased risk for development of cancer and other chronic diseases.^{68,90} Registry data suggest that some workers appear to be at an increased risk of developing sarcoidosis.⁵⁵

The Russian military used a mysterious “gas” to incapacitate Chechen rebels at a Moscow theatre in 2002, resulting in the deaths of more than 120 hostages. Although never publically indentified, the gas may have consisted of a highly potent aerosolized fentanyl derivative such as carfentanil and an inhalational anesthetic such as halothane. Better preparation of the rescuers with suitable amounts of naloxone may have helped prevent many of these seemingly unanticipated casualties.¹³¹

Ricin was found in several government buildings, including a mail- processing plant in Greenville, South Carolina, in 2003 and the Dirksen Senate Office Building in Washington, DC, in 2004. Although no cases of ricin-associated illness ensued, increased concern was generated because the method of delivery was thought to be the mail, and irradiation procedures designed to kill microbials such as anthrax would not inactivate chemical toxins such as ricin.^{14,111}

FOOD DISASTERS

Unintentional contamination of food and drink has led to numerous toxic disasters (Table 2–3). Ergot, produced by the fungus *Claviceps purpurea*, caused epidemic ergotism as the result of eating breads and cereals made from rye contaminated by *C. purpurea*. In some epidemics, convulsive manifestations predominated, and in others, gangrenous manifestations predominated.⁸² Ergot-induced severe vasospasm was thought to be responsible for both presentations.⁸¹ In 994 A.D., 40,000 people died in Aquitania, France, in one such epidemic.⁶⁶ Convulsive ergotism was initially described as a “fire which twisted the people,” and the term “St. Anthony’s fire” (*ignis sacer*) was used to refer to the excruciating burning pain experienced in the extremities that is an early manifestation of gangrenous ergotism. The events surrounding the Salem, Massachusetts, witchcraft trials have also been attributed to the ingestion of contaminated rye. The bizarre neuropsychiatric manifestations exhibited by some of the individuals associated with this event may have been caused by the hallucinogenic properties of ergotamine, a lysergic acid diethylamide (LSD) precursor.^{22,78}

TABLE 2–3. Food Disasters

<i>Toxin/Contaminant</i>	<i>Location</i>	<i>Date</i>	<i>Significance</i>
Ergot	Aquitania, France	994 A.D.	40,000 died in the epidemic
Ergot	Salem, MA	1692	Neuropsychiatric symptoms may be attributable to ergot
Lead	Devonshire, England	1700s	Colic from cider contaminated during production
Arsenious acid	France	1828	40,000 cases of polyneuropathy from contaminated wine and bread
Lead	Canada	1846	134 men died during the Franklin expedition, possibly because of contamination of food stored in lead cans
Arsenic	Staffordshire, England	1900	Contaminated sugar used in beer production
Cadmium	Japan	1939–1954	Itai-itai ("ouch-ouch") disease
Hexachlorobenzene	Turkey	1956	4000 cases of porphyria cutanea tarda
Methyl mercury	Minamata Bay, Japan	1950s	Consumption of organic mercury poisoned fish
Triorthocresyl phosphate	Meknes, Morocco	1959	Cooking oil adulterated with turbojet lubricant
Cobalt	Quebec City, Canada and others	1960s	Beer cardiomyopathy
Methylenedianiline	Epping, England	1965	Jaundice
Polychlorinated biphenyls	Japan	1968	Yusho ("rice oil disease")
Methyl mercury	Iraq	1971	>400 deaths from contaminated grain
Polybrominated biphenyls	Michigan	1973	92% of state contaminated through food chain
Polychlorinated biphenyls	Taiwan	1979	Yi-Cheng ("oil disease")
Rapeseed oil (denatured)	Spain	1981	Toxic oil syndrome affected 19,000 people
Arsenic	Buenos Aires	1987	Malicious contamination of meat; 61 people underwent chelation
Arsenic	Bangladesh and West Bengal, India	1990s–present	Contaminated ground water; millions exposed; 100,000s with symptoms; greatest mass poisoning in history
Tetramine	China	2002	Snacks deliberately contaminated, resulting in 42 deaths and 300 people with symptoms
Arsenic	Maine	2003	Intentional contamination of coffee; one death and 16 cases of illness
Nicotine	Michigan	2003	Deliberate contamination of ground beef; 92 people became ill
Melamine	China	2008	50,000 hospitalized from tainted infant formula

During the last half of the 20th century, unintentional mass poisoning from food and drink contaminated with toxic chemicals became all too common. One of the more unusual poisonings occurred in Turkey in 1956 when wheat seed intended for planting was treated with the fungicide hexachlorobenzene and then inadvertently used for human consumption. Approximately 4000 cases of porphyria cutanea tarda were attributed to the ingestion of this toxic wheat seed.¹¹²

Another example of chemical food poisoning took place in Epping, England, in 1965. In this incident, a sack of flour became contaminated with methylenedianiline when the chemical unintentionally spilled onto the flour during transport to a bakery. Subsequent ingestion of bread baked with the contaminated flour produced hepatitis in 84 people. This outbreak of toxic hepatitis became known as Epping jaundice.⁵⁹

The manufacture of polybrominated biphenyls (PBBs) in a factory that also produced food supplements for livestock resulted in the unintentional contamination of a large amount of livestock feed in Michigan in 1973.²³ Significant morbidity and mortality among the livestock population resulted, and increased human tissue concentrations of PBBs were reported,¹³⁸ although human toxicity seemed limited to vague constitutional symptoms and abnormal liver function test results.

The chemical contamination of rice oil in Japan in 1968 caused a syndrome called Yusho ("rice oil disease"). This occurred when heat-exchange fluid containing polychlorinated biphenyls (PCBs) and polychlorinated dibenzofurans (PCDFs) leaked from a heating pipe into the rice oil. More than 1600 people developed chloracne, hyperpigmentation, an

increased incidence of liver cancer, or adverse reproductive effects. In 1979 in Taiwan, 2000 people developed similar clinical manifestations after ingesting another batch of PCB-contaminated rice oil. This latter epidemic was referred to as Yu-Cheng (“oil disease”).⁵⁴

In another oil contamination epidemic, consumption of illegally marketed cooking oil in Spain in 1981 was responsible for a mysterious poisoning epidemic that affected more than 19,000 people and resulted in at least 340 deaths. Exposed patients developed a multisystem disorder referred to as toxic oil syndrome (or toxic epidemic syndrome), characterized by pneumonitis, eosinophilia, pulmonary hypertension, scleroderma-like features, and neuromuscular changes. Although this syndrome was associated with the consumption of rapeseed oil denatured with 2% aniline, the exact etiology was not definitively identified at the time. Subsequent investigations suggest that the fatty acid oleyl anilide may have been the putative xenobiotic.^{56,57,100}

In 1999, an outbreak of health complaints related to consuming Coca Cola occurred in Belgium, when 943 people, mostly children, complained of gastrointestinal (GI) symptoms, malaise, headaches, and palpitations after drinking Coca Cola.⁹⁴ Many of those affected complained of an “off taste” or bad odor to the soft drink. In some of the Coca Cola bottles, the carbon dioxide was contaminated with small amounts of carbonyl sulfide, which hydrolyzes to hydrogen sulfide, and may have been responsible for odor-triggered reactions. Mass psychogenic illness may have contributed to the large number of medical complaints because the concentrations of the carbonyl sulfide and hydrogen sulfide were very low and unlikely to cause systemic toxicity.³⁸

Epidemics of heavy metal poisoning from contaminated food and drink have also occurred throughout history. Epidemic lead poisoning is associated with many different vehicles of transmission, including leaden bowls, kettles, and pipes. A famous 18th-century epidemic was known as the Devonshire colic. Although the exact etiology of this disorder was unknown for many years, later evidence suggested that the ingestion of lead-contaminated cider was responsible.¹³⁰

Intentional chemical contamination of food may also occur. Multiple cases of metal poisoning occurred in Buenos Aires in 1987, when vandals broke into a butcher’s shop and poured an unknown amount of a 45% sodium arsenite solution over 200 kg of partly minced meat.¹⁰⁸ The contaminated meat was purchased by 718 people. Of 307 meat purchasers who submitted to urine sampling, 49 had urine arsenic concentrations of 76 to 500 µg/dL, and 12 had urine arsenic concentrations above 500 µg/dL (normal urine arsenic is <50–100 µg/dL).

Cases of deliberate mass poisoning have heightened concerns about food safety and security. In China in 2002, a jealous food vendor adulterated fried dough sticks, sesame cakes, and rice prepared in a rival’s snack bar by surreptitiously putting a large amount of tetramine (tetramethylene disulfotetramine) into the raw pastry material. More than 300 people who consumed these adulterated snacks became ill, and 42 died.²⁹ In Maine in 2003, a disillusioned parishioner contaminated the communal coffee pot at a church bake sale with arsenic. One victim died within 12 hours, and five others developed hypotension.¹³⁹ In 2003 in Michigan, 92 people became ill after ingesting contaminated ground beef deliberately contaminated with a nicotine pesticide by a supermarket employee.⁶

At the end of the 20th century and beginning the 21st century, what may be the greatest mass poisoning in history is occurring in Bangladesh and India’s West Bengal State.^{32,87,104,121} (See Chap. 89.) In Bangladesh alone, 60 million people are routinely drinking arsenic-contaminated ground water and at least 220,000 inhabitants of India’s West Bengal have been diagnosed with arsenic poisoning.⁸⁶ Symptoms reported include melanosis, depigmentation, hyperkeratosis, hepatomegaly, splenomegaly, squamous cell carcinoma, intraepidermal carcinoma, and gangrene.³² In a country long plagued by dysentery, attempts to purify the water supply led to the drilling of millions of wells into the superficial water table. Unknown to the engineers, this water was naturally contaminated with arsenic, creating several thousand tube wells with extremely high concentrations of arsenic—up to 40 times the acceptable concentration. Although toxicity from arsenic-contaminated groundwater was previously reported from other areas of the world, including Argentina, China, Mexico, Taiwan (black foot disease), and Thailand, the number of people at risk in Bangladesh and West Bengal is by far the largest.

Methyl mercury is responsible for several poisoning epidemics in the past half century. During the 1950s, a Japanese chemical factory that manufactured vinyl chloride and acetaldehyde routinely discharged mercury into Minamata Bay, resulting in contamination of the aquatic food chain. An epidemic of methyl mercury poisoning ensued as the local people ate the poisoned fish.^{101,126} Chronic brain damage, tunnel vision, deafness, and severe congenital defects were associated with this mass poisoning.¹⁰¹ Another mass epidemic of methyl mercury poisoning occurred in Iraq in 1971, when the local population consumed homemade bread prepared from wheat seed treated with a methyl mercury fungicide.¹⁵ Six thousand hospital admissions and more than 400 deaths were associated with this mass poisoning. As was the case of the hexachlorobenzene exposure in Turkey 15 years previously, the treated grain, intended for use as seed, was instead used as food.

From 1939 to 1954, contamination of the local water supply with the wastewater runoff from a zinc–lead–cadmium mine in Japan was believed responsible for causing Itai-Itai (“ouch-ouch”) disease, an unusual chronic syndrome manifested by extreme bone pain and osteomalacia. The local water was used for drinking and irrigation of the rice fields. Approximately 200 people who lived along the banks of the Jintsu River developed these peculiar symptoms, which were

thought most likely to be caused by the cadmium.²

More than 50,000 infants were hospitalized in China in 2008 from the ill effects of melamine-contaminated powdered infant formulas.⁵² Melamine (1,3,5-triazine–2,4,6-triamine) is a component in many adhesives, glues, plastics, and laminated products (eg, plywood, cleaners, cement, cleansers, and fire-retardant paint). More than 20 Chinese companies produced the tainted formula. Analysis of these formulas found melamine concentrations as high as 2500 ppm. Clinically, exposure to high doses of melamine has been associated with the development of nephrolithiasis; obstructive uropathy; and in some cases, acute kidney failure. Melamine contamination of pet food resulting in deaths in dogs and cats had previously been reported.²¹ The melamine disaster also demonstrates that globalization and international agribusiness may facilitate worldwide distribution of contaminated foodstuffs. After the initial reports of melamine contamination in China, investigation in the United States revealed that certain brands of cookies, biscuits, candies, and milk sold in this country were also tainted with melamine, some of which was traced to an origin in China.⁵²

MEDICINAL DRUG DISASTERS

Illness and death as a consequence of therapeutic drug use occur as sporadic events, usually affecting individual patients, or as mass poisoning, affecting multiple (sometimes hundreds or thousands) patients. Sporadic single-patient medication-induced tragedies usually result from errors ([Chaps. 1 and 140](#)) or unforeseen idiosyncratic reactions. Mass therapeutic drug disasters have generally occurred secondary to poor safety testing, a lack of understanding of diluents and excipients, drug contamination, or problems with unanticipated drug–drug interactions or drug toxicity ([Table 2–4](#)).

TABLE 2–4. Medicinal Disasters

<i>Xenobiotic</i>	<i>Location</i>	<i>Date</i>	<i>Significance</i>
Thallium	US	1920s–1930s	Treatment of ringworm; 31 deaths
Diethylene glycol	US	1937	Elixir of sulfanilamide; kidney failure
Thorotrast	US	1930s–1950s	Hepatic angiosarcoma
Phenobarbital	US	1940–1941	Contaminated sulfathiazole; 82 deaths
Diethylstilbestrol (DES)	US, Europe	1940s–1970s	Vaginal adenocarcinoma in patients' daughters
Stalmon	France	1954	Severe neurotoxicity from triethyltin
Cloquinal	Japan	1955–1970	Subacute myelo-optic neuropathy (SMON); 10,000 symptomatic
Thalidomide	Europe	1960s	5000 cases of phocomelia
Isoproterenol 30%	Great Britain	1961–1967	3000 excess asthma deaths
Pentachlorophenol	US	1967	Used in hospital laundry; nine neonates ill, two deaths
Benzyl alcohol	US	1981	Neonatal gasping syndrome
Tylenol–cyanide	Chicago	1982	Tampering incident resulted in seven homicides
L-Tryptophan	US	1989	Eosinophilia myalgia syndrome
Diethylene glycol (DEG)	Haiti	1996	APAP elixir contaminated; kidney failure; >88 pediatric deaths
Diethylene glycol	Panama	2006	Contaminated cough preparation, causing 78 deaths
Diethylene glycol	Nigeria	2009	Contaminated teething formula, causing 84 deaths

In September and October 1937, more than 105 deaths were associated with the use of one of the early sulfa preparations—elixir of sulfanilamide–Massengill—that contained 72% diethylene glycol as the vehicle for drug delivery. Little was known about diethylene glycol toxicity at the time, and many cases of acute kidney failure and death occurred.⁴⁰ To avoid similar tragedies in the future, animal drug testing was mandated by the Food, Drug, and Cosmetic Act of 1938.¹³² Unfortunately, diethylene glycol continues to be sporadically used in other countries as a medicinal diluent, resulting in deaths in South Africa (1969), India (1986), Nigeria (1990), Bangladesh (1990–1992), and Haiti (1995–1996).¹³³ In 1996 in Haiti, at least 88 Haitian children died (case fatality rate of 98% for those who remained in Haiti) after ingesting an

acetaminophen (APAP) elixir formulated with diethylene glycol–contaminated glycerin.^{95,110} In Panama in 2006, glycerin contaminated with diethylene glycol found in prescription liquid cough syrup resulted in at least 121 cases of poisoning and 78 deaths (case fatality rate, 65.5%).^{18,106} Investigators of this last outbreak discovered that the contaminated glycerin was imported to Panama from China via a European broker, demonstrating that improprieties in pharmaceutical manufacturing may have worldwide implications. In Nigeria in 2009, a tainted teething formula was responsible for 84 deaths in children.⁷ The pharmaceutical manufacturers intended to purchase propylene glycol, a component of the teething formula, but had bought the diluent in a jerrycan instead of the original container, and the chemical contained diethylene glycol (Special Considerations: SC7).

A lesser known drug manufacturing event, also involving an early sulfa antimicrobial, occurred in 1940 to 1941, when at least 82 people died from the therapeutic use of sulfathiazole that was contaminated with phenobarbital (Luminal).¹²² The responsible pharmaceutical company, Winthrop Chemical, produced both sulfathiazole and phenobarbital, and the contamination likely occurred during the tableting process because the tableting machines for the two medications were adjacent to each other and were used interchangeably. Each contaminated sulfathiazole tablet contained about 350 mg of phenobarbital (and no sulfathiazole), and the typical sulfathiazole dosing regimen was several tablets within the first few hours of therapy. Twenty-nine percent of the production lot was contaminated. Food and Drug Administration (FDA) intervention was required to assist with the recovery of the tablets, although 22,000 contaminated tablets were never found.¹²²

In the early 1960s, one of the worst drug-related modern-day events occurred with the release of thalidomide as an antiemetic and sedative–hypnotic.³¹ Its use as a sedative–hypnotic by pregnant women caused about 5000 babies to be born with severe congenital limb anomalies.⁸² This tragedy was largely confined to Europe, Australia, and Canada, where the drug was initially marketed. The United States was spared because of the length of time required for review and the rigorous scrutiny of new drug applications by the FDA.⁷⁹

A major therapeutic drug event that did occur in the United States involved the recommended and subsequent widespread use of diethylstilbestrol (DES) for the treatment of threatened and habitual abortions. Despite the lack of convincing efficacy data, as many as 10 million Americans received DES during pregnancy or in utero during a 30-year period, until the drug was prohibited for use during pregnancy in 1971. Adverse health effects associated with DES use include increased risk for breast cancer in “DES mothers” and increased risk of a rare form of vaginal cancer, reproductive tract anomalies, and premature births in “DES daughters.”^{42,46}

Thorotrast (thorium dioxide 25%) is an intravenous radiologic contrast medium that was widely used between 1928 and 1955. Its use was associated with the delayed development of hepatic angiosarcomas, as well as skeletal sarcomas, leukemia, and “thorotrastomas” (malignancies at the site of extravasated thorotrast).^{120,134}

The use of thallium to treat ringworm infections in the 1920s and 1930s also led to needless morbidity and mortality.⁴³ Understanding that thallium caused alopecia, dermatologists and other physicians prescribed thallium acetate, both as pills and as a topical ointment (Koremlu), to remove the infected hair. A 1934 study found 692 cases of thallium toxicity after oral and topical application and 31 deaths after oral use.⁸⁹ “Medicinal” thallium was subsequently removed from the market.

The “Stalinon affair” in France in 1954 involved the unintentional contamination of a proprietary oral medication that was marketed for the treatment of staphylococcal skin infections, osteomyelitis, and anthrax. Although it was supposed to contain diethyltin diiodide and linoleic acid, triethyltin, a potent neurotoxin and the most toxic of organotin compounds, and trimethyltin were present as impurities. Of the approximately 1000 people who received this medication, 217 patients developed symptoms, and 102 patients died.^{10,17}

An unusual syndrome, featuring a constellation of abdominal symptoms (pain and diarrhea) followed by neurologic symptoms (peripheral neuropathy and visual disturbances, including blindness) was experienced by approximately 10,000 Japanese people between 1955 and 1970, resulting in several hundred deaths.⁶² This presentation, subsequently labeled subacute myelo-optic neuropathy (SMON), was associated with the use of the GI disinfectant clioquinol, known in the West as Entero-Vioform and most often used for the prevention of travelers’ diarrhea.⁹² In Japan, this drug was referred to as sei-cho-zai (“active in normalizing intestinal function”). It was incorporated into more than 100 nonprescription medications and was used by millions of people, often for weeks or months. The exact mechanism of toxicity has not been determined, but recent investigators theorize that clioquinol may enhance the cellular uptake of certain metals, particularly zinc, and that the clioquinol–zinc chelate may act as a mitochondrial toxin, causing this syndrome.¹³ New cases declined rapidly when clioquinol was banned in Japan.

In 1981, a number of premature neonates died with a “gasping syndrome,” manifested by severe metabolic acidosis, respiratory depression with gasping, and encephalopathy.⁴¹ Before the development of these findings, the infants had all received multiple injections of heparinized bacteriostatic sodium chloride solution (to flush their indwelling catheters) and bacteriostatic water (to mix medications), both of which contained 0.9% benzyl alcohol. Accumulation of large amounts of benzyl alcohol and its metabolite benzoic acid in the blood was thought to be responsible for this syndrome.⁴¹

In 1989 and 1990, eosinophilia-myalgia syndrome, a debilitating syndrome somewhat similar to toxic oil syndrome, developed in more than 1500 people who had used the dietary supplement L-tryptophan.¹²⁸ These patients presented with disabling myalgias and eosinophilia, often accompanied by extremity edema, dyspnea, and arthralgias. Skin changes, neuropathy, and weight loss sometimes developed. Intensive investigation revealed that all affected patients had ingested L-tryptophan produced by a single manufacturer that had recently introduced a new process involving genetically altered bacteria to improve L-tryptophan production. A contaminant produced by this process probably was responsible for this syndrome.²⁰ The banning of L-tryptophan by the FDA set in motion the passage of the Dietary Supplement Health and Education Act of 1994. This legislation, which attempted to regulate an uncontrolled industry, facilitated industry marketing of dietary supplements bypassing FDA scrutiny. In 2001, the FDA loosened the restrictions on the marketing of tryptophan, which is now sold through some compounding pharmacies.

A number of pharmaceuticals previously approved by the FDA have been withdrawn from the market because of concerns about health risks.¹⁴¹ Many more drugs have been given “black box warnings” by the FDA because of their propensity to cause serious or life-threatening adverse effects.⁷⁷ Some of the withdrawn drugs had been responsible for causing serious drug–drug interactions (astemizole, cisapride, mibefradil, terfenadine).⁸⁸ Other drugs were withdrawn because of a propensity to cause hepatotoxicity (troglitazone), anaphylaxis (bromfenac sodium), valvular heart disease (fenfluramine, dexfenfluramine), rhabdomyolysis (cerivastatin), hemorrhagic stroke (phenylpropanolamine), and other adverse cardiac and neurologic effects (ephedra, rofecoxib). One of the more disconcerting drug problems to arise was the development of cardiac valvulopathy and pulmonary hypertension in patients taking the weight-loss drug combination fenfluramine and phentermine (fen-phen) or dexfenfluramine.^{27,116} The histopathologic features observed with this condition were similar to the valvular lesions associated with ergotamine and carcinoid syndrome. Interestingly, appetite suppressant medications, as well as ergotamine and carcinoid, all increase available serotonin.

ALCOHOL AND ILLICIT DRUG DISASTERS

Unintended toxic disasters have also involved the use of alcohol and other drugs of abuse (Table 2–5). Arsenical neuropathy developed in an estimated 40,000 people in France in 1828, when wine and bread were unintentionally contaminated by arsenious acid.⁷⁶ The use of arsenic-contaminated sugar in the production of beer in England in 1900 resulted in at least 6000 cases of peripheral neuropathy and 70 deaths (Staffordshire beer epidemic).⁵

TABLE 2–5. Alcohol and Illicit Drug Disasters

<i>Xenobiotic</i>	<i>Location</i>	<i>Date</i>	<i>Significance</i>
Triorthocresyl phosphate	US	1930–1931	Ginger Jake paralysis
Methanol	Atlanta, GA	1951	Epidemic from ingesting bootleg whiskey
Methanol	Jackson, MI	1979	Occurred in a prison
MPTP	San Jose, CA	1982	Illicit meperidine manufacturing resulting in drug-induced parkinsonism
Heroin heated on aluminum foil	Netherlands	1982	Spongiform leukoencephalopathy
3-Methyl fentanyl	Pittsburgh, PA	1988	“China-white” epidemic
Methanol	Baroda, India	1989	Moonshine contamination; 100 deaths
Fentanyl	New York City	1990	“Tango and Cash” epidemic
Methanol	New Delhi, India	1991	Antidiarrheal medication contaminated with methanol; >200 deaths
Methanol	Cuttack, India	1992	Methanol-tainted liquor; 162 deaths
Scopolamine	US East Coast	1995–1996	325 cases of anticholinergic poisoning in heroin users
Methanol	Cambodia	1998	>60 deaths
Methanol	Nicaragua	2006	800 became ill, 15 blind, 45 deaths
Methanol	India	2011	>143 deaths

MPTP = 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

During the early 20th century, particularly during Prohibition, the ethanolic extract of Jamaican ginger (sold as “the

Jake”) was a popular ethanol substitute in the southern and midwestern United States.⁸³ It was sold legally because it was considered a medical supplement to treat headaches and aid digestion and was not subject to Prohibition. For years, the Jake was sold adulterated with castor oil, but in 1930, as the price of castor oil rose, the Jake was reformulated with an alternative adulterant, triorthocresyl phosphate (TOCP). Little was previously known about the toxicity of this compound, and TOCP proved to be a potent neurotoxin. From 1930 to 1931, at least 50,000 people who drank the Jake developed TOCP poisoning, manifested by upper and lower extremity weakness (“ginger Jake paralysis”) and gait impairment (“Jake walk” or “Jake leg”).⁸³ A quarter century later, in Morocco, the dilution of cooking oil with a turbojet lubricant containing TOCP caused an additional 10,000 cases of TOCP-induced paralysis.¹¹⁹

In the 1960s, cobalt was added to several brands of beer as a foam stabilizer. Certain local breweries in Quebec City, Canada; Minneapolis, Minnesota; Omaha, Nebraska; and Louvain, Belgium added 0.5–5.5 ppm cobalt to their beer. This resulted in epidemics of fulminant heart failure among heavy beer drinkers (named cobalt–beer cardiomyopathy).^{1,84}

Epidemic methanol poisoning among those seeking ethanol and other inebriants is well described. In one such incident in Atlanta, Georgia, in 1951, the ingestion of methanol-contaminated bootleg whiskey caused 323 cases of methanol poisoning, including 41 deaths. In another epidemic in 1979, 46 prisoners became ill after ingesting a methanol-containing diluent used in copy machines.¹²³

In recent years, major mass methanol poisonings have continued to occur in developing countries, where store-bought alcohol is often prohibitively expensive. In Baroda, India, in 1989, at least 100 people died and another 200 became ill after drinking a homemade liquor that was contaminated with methanol.⁴ In New Delhi, India, in 1991, an inexpensive antidiarrheal medicine, advertised to contain large amounts of ethanol, was instead contaminated with methanol, causing more than 200 deaths.²⁶ The following year, in Cuttack, India, 162 people died and an additional 448 were hospitalized after drinking methanol-tainted liquor.¹¹ A major epidemic of methanol poisoning occurred in 1998 in Cambodia, when rice wine was contaminated with methanol.³ At least 60 deaths and 400 cases of illness were attributed to the methanol. In 2011 in Sangrampur, India, more than 143 died from drinking methanol tainted bootleg alcohol.⁷¹

So-called “designer drugs” are responsible for several toxicologic disasters. In 1982, several injection drug users living in San Jose, California, who were attempting to use a meperidine analog MPPP (1-methyl-4-phenyl-4-propionyloxy-piperidine) developed a peculiar, irreversible neurologic disease closely resembling Parkinson disease.⁶⁴ Investigation revealed that these patients had unknowingly injected trace amounts of MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), which was present as an inadvertent product of the clandestine MPPP synthesis. The subsequent metabolism of MPTP to MPP⁺ resulted in a toxic compound that selectively destroyed cells in the substantia nigra depleting dopamine stores or products causing severe and irreversible parkinsonism. The vigorous pursuit of the cause of this disaster led to a better understanding of the pathophysiology of parkinsonism.

Another example of a “designer drug” poisoning occurred in the New York City metropolitan area in 1991, when a sudden epidemic of opioid overdoses occurred among heroin users who bought envelopes labeled “Tango and Cash.”³⁷ Expecting to receive a new brand of heroin, the drug users instead purchased the much more potent fentanyl. Increased and unpredictable toxicity resulted from the inability of the dealer to adjust (“cut”) the fentanyl dose properly. Some purchasers presumably received little or no fentanyl, but others received potentially lethal doses. A similar epidemic involving 3-methylfentanyl occurred in 1988 in Pittsburgh, Pennsylvania and continue to occur in the United States in the 21st Century.⁷⁴

At least 325 cases of anticholinergic poisoning occurred among heroin users in New York City; Newark, New Jersey; Philadelphia, Pennsylvania; and Baltimore, Maryland from 1995 to 1996.⁸ The “street drug” used in these cases was adulterated with scopolamine. Whereas naloxone treatment was associated with increased agitation and hallucinations, physostigmine administration resulted in resolution of symptoms. Why the heroin was adulterated was unknown, although the use of an opiate–scopolamine mixture was reminiscent of the morphine–scopolamine combination therapy known as “twilight sleep” that was extensively used in obstetric anesthesia during the early 20th century.⁹⁸ Another unexpected complication of heroin use was observed in the Netherlands in the 1980s, when 47 heroin users developed mutism and spastic quadriparesis that was pathologically documented to be spongiform leukoencephalopathy.¹⁴⁰ In these and subsequent cases in Europe and the United States, the users inhaled heroin vapors after the heroin powder had been heated on aluminum foil, a drug administration technique known as “chasing the dragon.”^{60,140} The exact toxic mechanism has not been elucidated.

OCCUPATION-RELATED CHEMICAL DISASTERS

Unfortunately, occupation-related toxic epidemics have become increasingly common (Table 2–6). Such poisoning syndromes tend to have an insidious onset and may not be recognized clinically until years after the exposure. A specific xenobiotic may cause myriad problems, among the most worrisome being the carcinogenic and mutagenic potentials.

TABLE 2–6. Occupational Disasters

<i>Xenobiotic</i>	<i>Location</i>	<i>Date</i>	<i>Significance</i>
Polycyclic aromatic hydrocarbons	England	1700s	Scrotal cancer among chimney sweeps; first description of hydrocarbons occupational cancer
Mercury	New Jersey	Mid to late 1800s	Outbreak of mercurialism in hatters
White phosphorus	Europe	Mid to late 1800s	Phossy jaw in matchmakers
β -Naphthylamine	Worldwide	Early 1900s	Bladder cancer in dye makers
Benzene	Newark, NJ	1916–1928	Aplastic anemia among artificial leather manufacturers
Asbestos	Worldwide	20th century	Millions at risk for asbestos-related disease
Vinyl chloride	Louisville, KY	1960s–1970s	Hepatic angiosarcoma among plastics workers
Chlordecone	James River, VA	1973–1975	Neurologic abnormalities among insecticide workers
1,2-Dibromochloropropane	California	1974	Infertility among pesticide makers

Although the 18th-century observations of Ramazzini and Pott introduced the concept of certain diseases as a direct result of toxic exposures in the workplace, it was not until the height of the 19th-century industrial revolution that the problems associated with the increasingly hazardous workplace became apparent.⁵¹ During the 1860s, a peculiar disorder, attributed to the effects of inhaling mercury vapor, was described among manufacturers of felt hats in New Jersey.¹³⁵ Mercury nitrate was used as an essential part of the felting process at the time. “Hatter’s shakes” refers to the tremor that developed in an estimated 10% to 60% of hatters surveyed.¹³⁵ Extreme shyness, another manifestation of mercurialism, also developed in many hatters in later studies. Five percent of hatters during this period died from kidney failure.

Other notable 19th-century and early 20th-century occupational tragedies included an increased incidence of mandibular necrosis (phossy jaw) among workers in the matchmaking industry who were exposed to white phosphorus,⁴⁹ an increased incidence of bladder tumors among synthetic dye makers who used β -naphthylamine,⁴⁴ and an increased incidence of aplastic anemia among artificial leather manufacturers who used benzene.¹¹⁴ The epidemic of phossy jaw among matchmakers had a latency period of 5 years and a mortality rate of 20% and has been called the “greatest tragedy in the whole story of occupational disease.”²⁴ The problem continued in the United States until Congress passed the White Phosphorus Match Act in 1912, which established a prohibitive tax on white phosphorus matches.

Since antiquity, occupational lead poisoning has been a constant threat. Workplace exposure to lead was particularly problematic during the 19th century and early 20th century because of the large number of industries that relied heavily on lead. One of the most notorious of the “lead trades” was the actual production of white lead and lead oxides. Palsies, encephalopathy, and death from severe poisoning were reported.⁴⁵ Other occupations that resulted in dangerous lead exposures included pottery glazing, rubber manufacturing, pigment manufacturing, painting, printing, and plumbing.⁷³ Given the increasing awareness of harm suffered in the workplace, the British Factory and Workshop Act of 1895 required governmental notification of occupational diseases caused by lead, mercury, and phosphorus poisoning, as well as of occupational diseases caused by anthrax.⁶⁵

Exposures to asbestos during the 20th century have resulted in continuing extremely consequential occupational and environmental disasters.^{28,91} Even though the first case of asbestosis was reported in 1907, asbestos was heavily used in the shipbuilding industries in the 1940s as an insulating and fireproofing material. Since the early 1940s, 8 to 11 million individuals were occupationally exposed to asbestos,⁶⁷ including 4.5 million individuals who worked in the shipyards. Asbestos-related diseases include mesothelioma, lung cancer, and pulmonary fibrosis (asbestosis). A threefold excess of cancer deaths, primarily of excess lung cancer deaths, has been observed in asbestos-exposed insulation workers.¹¹³

The manufacture and use of a variety of newly synthesized chemicals has also resulted in mass occupational poisonings. In Louisville, Kentucky in 1974, an increased incidence of angiosarcoma of the liver was first noticed among polyvinyl chloride polymerization workers who were exposed to vinyl chloride monomer.³⁵ In 1975, chemical factory workers exposed to the organochlorine insecticide chlordecone (Kepone) experienced a high incidence of neurologic abnormalities, including tremor and chaotic eye movements.¹²⁴ An increased incidence of infertility among male Californian pesticide workers exposed to 1,2-dibromochloropropane (DBCP) was noted in 1977.¹³⁶

RADIATION DISASTERS

A discussion of mass poisonings is incomplete without mention of the large number of radiation disasters that have

characterized the 20th century (Table 2–7). The first significant mass exposure to radiation occurred among several thousand teenage girls and young women employed in the dial-painting industry.²⁵ These workers painted luminous numbers on watch and instrument dials with paint that contained radium. Exposure occurred by licking the paint brushes and inhaling radium-laden dust. Studies showed an increase in bone-related cancers, as well as aplastic anemia and leukemia, in exposed workers.^{75,99}

TABLE 2–7. Radiation Disasters

<i>Xenobiotic</i>	<i>Location</i>	<i>Date</i>	<i>Significance</i>
Radium	Orange, NJ	1910s–1920s	Increase in bone cancer in dial-painting workers
Radium	US	1920s	“Radithor” (radioactive water) sold as radium-containing patent medication
Radiation	Hiroshima and Nagasaki, Japan	1945	First atomic bombs dropped at the end of World War II; clinical effects still evident today
Radiation	Chernobyl, Ukraine	1986	Unintentional radioactive release; acute radiation sickness
Cesium	Goiania, Brazil	1987	Acute radiation sickness and radiation burns
Cesium, iodine	Fukushima, Japan	2011	Unintentional radioactive release after earthquake and tsunami

At the time of the “watch” disaster, radium was also being sold as a nostrum touted to cure all sorts of ailments, including rheumatism, syphilis, multiple sclerosis, and sexual dysfunction. Referred to as “mild radium therapy” to differentiate it from the higher dose radium that was used in the treatment of cancer at that time, such particle-emitting isotopes were hailed as powerful natural elixirs that acted as metabolic catalysts to deliver direct energy transfusions.⁷⁰

During the 1920s, dozens of patent medications containing small doses of radium were sold as radioactive tablets, liniments, or liquids. One of the most infamous preparations was Radithor. Each half-ounce bottle contained slightly more than one curie of radium-228 and radium-226. This radioactive water was sold all over the world “as harmless in every respect” and was heavily promoted as a sexual stimulant and aphrodisiac, taking on the glamour of a recreational drug for the wealthy.⁷⁰ More than 400,000 bottles were sold. The 1932 death of Eben Byers, a Radithor connoisseur, from chronic radiation poisoning drew increased public and governmental scrutiny to this unregulated radium industry and helped end the era of radioactive patent medications.⁷⁰

Concerns about the health effects of radiation have continued to escalate since the dawn of the nuclear age in 1945. Long-term follow-up studies 50 years after the atomic bombings at Hiroshima and Nagasaki demonstrate an increased incidence of leukemia, other cancers, radiation cataracts, hyperparathyroidism, delayed growth and development, and chromosomal anomalies in exposed individuals.⁵⁸

The unintentional nuclear disaster at Chernobyl, Ukraine, in April 1986 again forced the world to confront the medical consequences of 20th-century scientific advances that created the atomic age.³⁹ The release of radioactive material resulted in 31 deaths and the hospitalization of more than 200 people for acute radiation sickness. By 2003, the predominant long-term effects of the event appeared to be childhood thyroid cancer and psychological consequences.¹⁰⁵ In some areas of heavy contamination, the increase in childhood thyroid cancer has increased 100-fold.¹⁰⁹

Another serious radiation event occurred in Goiania, Brazil, in 1987 when an abandoned radiotherapy unit was opened in a junkyard and 244 people were exposed to cesium-137. Of those exposed, 104 showed evidence of internal contamination, 28 had local radiation injuries, and eight developed acute radiation syndrome. There were at least four deaths.^{97,107}

In September 1999, a nuclear event at a uranium-processing plant in Japan set off an uncontrolled chain reaction, exposing 49 people to radiation.⁶¹ Radiation measured outside the facility reached 4000 times the normal ambient level. Two workers died from the effects of the radiation.

A 9.0 magnitude earthquake and tsunami in Japan in March 2011 caused equipment failure at the Fukushima Daiichi nuclear plant resulted in a release of radioactive material into the atmosphere and seawater. Nearby foodstuff and drinking

water were contaminated with Cesium-137 and Iodine-131.¹²⁵

MASS SUICIDE BY POISON

Mass poisonings have also manifested themselves as events of mass suicide. In 1978 in Jonestown, Guyana, 911 members of the Peoples Temple died after drinking a beverage containing cyanide.¹² In 1997, phenobarbital and ethanol (sometimes assisted by physical asphyxiation) was the suicidal method favored by 39 members of the Heavens Gate cult in Rancho Santa Fe, California, a means of suicide recommended in the book *Final Exit*.⁵⁰ Apparently, the cult members committed suicide to shed their bodies in hopes of hopping aboard an alien spaceship they believed was in the wake of the Hale-Bopp comet.⁶³

SUMMARY

- There are significant lessons to be learned from mass poisonings.
- An understanding of the pathogenesis of these mass poisonings pertaining to drug, food, and occupational safety is critically important to prevent future disasters.
- Such events make us aware that many of the toxic xenobiotics involved are potential agents of opportunity for terrorists and others who invoke harm.
- Given the practical and ethical limitations in studying the effects of many specific xenobiotics in humans, lessons from these unfortunate tragedies must be fully mastered and retained for future generations.

PART A

**THE GENERAL APPROACH TO MEDICAL
TOXICOLOGY**

3 INITIAL EVALUATION OF THE PATIENT: VITAL SIGNS AND TOXIC SYNDROMES

Robert S. Hoffman, Mary Ann Howland, Neal A. Lewin, Lewis S. Nelson,
and Lewis R. Goldfrank

For more than 200 years, American health care providers have attempted to standardize their approach to the assessment of patients. At the New York Hospital in 1865, pulse rate, respiratory rate, and temperature were incorporated into the bedside chart and called “vital signs.”⁶ It was not until the early part of the 20th century, however, that blood pressure determination also became routine. Additional components of the standard emergency assessment, such as oxygen saturation by pulse oximetry, capillary blood glucose, and pain severity, are now also beginning to be considered vital signs. Although assessment of oxygen saturation, capillary glucose, and pain severity are essential components of the clinical evaluation and are important considerations throughout this text, they are not discussed in this chapter.

In the practice of medical toxicology, vital signs play an important role beyond assessing and monitoring the overall status of a patient because they frequently provide valuable physiologic clues to the toxicologic etiology and severity of an illness. The vital signs also are a valuable parameter, which are used to assess and monitor a patient’s response to supportive treatment and antidotal therapy.

Table 3–1 presents the normal vital signs for various age groups. However, this broad range of values considered normal should serve merely as a guide. Only a complete assessment of a patient can determine whether or not a particular vital sign is truly clinically normal. This table of normal vital signs is useful in assessing children because normal values for children vary considerably with age, and knowing the range of normal variation is essential. Normal rectal temperature is defined as 95° to 100.4°F (35°–38°C).

TABLE 3–1. Normal Vital Signs by Age^{a,b}

Age	Systolic BP (mm Hg)	Diastolic BP (mm Hg)	Pulse (beats/min)	Respirations (breaths/min) ^b
Adult	≤120	<80	60–100	16–24
16 years	≤120	<80	80	16–30
12 years	119	76	85	16–30
10 years	115	74	90	16–30
6 years	107	69	100	20–30
4 years	104	65	110	20–30
4 months	90	50	145	30–35
2 months	85	50	145	30–35
Newborn	65	50	145	35–40

^aThe normal rectal temperature is defined as 95°F to 100.4°F (35°–38°C) for all ages. For children one year of age or younger, these values are the mean values for the 50th percentile. For older children, these values represent the 90th percentile at a specific age for the 50th percentile of weight in that age group. ^bThese values were determined in the emergency department and may be environment and situation dependent.

BP = blood pressure.

The difficulty in defining what constitutes “normal” vital signs in an emergency setting is inadequately addressed and may prove to be an impossible undertaking. Published normal values may have little relevance for an acutely ill or anxious

patient in the emergency setting, yet that is precisely the environment in which we must define abnormal vital signs and address them accordingly. Even in nonemergent situations, “normalcy” of vital signs depends on the clinical condition of the patient. A sleeping or comatose patient may have physiologic bradycardia; a slow heart rate appropriate for his or her low energy requiring state. For these reasons, descriptions of vital signs as “normal” or “stable” are too nonspecific to be meaningful and therefore should never be accepted as defining normalcy in an individual patient. Conversely, no patient should be considered too agitated, too young, or too gravely ill to obtain a complete set of vital signs; indeed, these patients urgently need a thorough evaluation that includes all of the vital signs. Also, the vital signs must be recorded as accurately as possible first in the prehospital setting, again with precision and accuracy as soon as a patient arrives in the emergency department (ED), and serially thereafter as clinically indicated.

Many xenobiotics affect the autonomic nervous system, which, in turn, affects the vital signs via the sympathetic pathway, the parasympathetic pathway, or both. Meticulous attention to both the initial and repeated determinations of vital signs is of extreme importance in identifying a pattern of changes suggesting a particular xenobiotic or group of xenobiotics. The value of serial monitoring of the vital signs is demonstrated by the patient who presents with an anticholinergic overdose who is then given the antidote, physostigmine. In this situation, it is important to recognize when tachycardia becomes bradycardia (ie, anticholinergic syndrome followed by physostigmine excess). Meticulous attention to these changes ensures that the therapeutic interventions can be modified or adjusted accordingly.

Similarly, consider the course of a patient who has opioid-induced bradypnea (a decreased rate of breathing) and then develops tachypnea (an increased rate of breathing) after the administration of the opioid antagonist naloxone. The analysis becomes exceedingly complicated when that patient may have been exposed to two or more xenobiotics, such as an opioid combined with cocaine. In this situation, the effects of cocaine may be “unmasked” by the naloxone used to counteract the opioid, and the clinician must then be forced to differentiate naloxone-induced opioid withdrawal from cocaine toxicity. The assessment starts by analyzing diverse information, including vital signs, history, and physical examination.

Table 3–2 describes the most typical toxic syndromes. This table includes only vital signs that are thought to be characteristically abnormal or pathognomonic and directly related to the toxicologic effect of the xenobiotic. The primary purpose of the table, however, is to include many findings, in addition to the vital signs, that together constitute a toxic syndrome. Mofenson and Greensher⁵ coined the term toxidromes from the words toxic syndromes to describe the groups of signs and symptoms that consistently result from particular toxins. These syndromes are usually best described by a combination of the vital signs and clinically apparent end-organ manifestations. The signs that prove most clinically useful are those involving the central nervous system (CNS; mental status), ophthalmic system (pupil size), gastrointestinal system (peristalsis), dermatologic system (skin dryness versus diaphoresis), mucous membranes (moistness versus dryness), and genitourinary system (urinary retention versus incontinence). Table 3–2 includes some of the most important signs and symptoms and the xenobiotics most commonly responsible for these manifestations. A detailed analysis of each sign, symptom, and toxic syndrome can be found in the pertinent chapters throughout the text. In this chapter, the most typical toxic syndromes are considered to enable the appropriate assessment and differential diagnosis of a poisoned patient.

TABLE 3–2. Toxic Syndromes

Group	Vital Signs				Mental Status	Pupil Size	Peristalsis	Diaphoresis	Other
	BP	P	R	T					
Anticholinergics	–/↑	↑	±	↑	Delirium	↑	↓	↓	Dry mucous membranes, flush, urinary retention
Cholinergics	±	±	–/↑	–	Normal to depressed	±	↑	↑	Salivation, lacrimation, urination, diarrhea, bronchorrhea, fasciculations, paralysis
Ethanol or sedative–hypnotics	↓	↓	↓	–/↓	Depressed, agitated	±	↓	–	Hyporeflexia, ataxia
Opioids	↓	↓	↓	↓	Depressed	↓	↓	–	Hyporeflexia
Sympathomimetics	↑	↑	↑	↑	Agitated	↑	–/↑	↑	Tremor, seizures
Withdrawal from ethanol or sedative–hypnotics	↑	↑	↑	↑	Agitated, disoriented, hallucinations	↑	↑	↑	Tremor, seizures
Withdrawal from opioids	↑	↑	–	–	Normal, anxious	↑	↑	↑	Vomiting, rhinorrhea, piloerection, diarrhea, yawning

↑ = increases; ↓ = decreases; ± = variable; – = change unlikely; BP = blood pressure; P = pulse; R = respirations; T = temperature.

In considering a toxic syndrome, the reader should always remember that the actual clinical manifestations of a poisoning are far more variable than the syndromes described in Table 3–2. The concept of the toxic syndrome is most

useful when thinking about a clinical presentation and formulating a framework for assessment. Although some patients may present as “classic” cases, others manifest partial toxic syndromes or formes frustes. These incomplete syndromes may still provide at least a clue to the correct diagnosis. It is important to understand that partial presentations (particularly in the presence of multiple xenobiotics) do not necessarily imply less severe disease and, therefore, are comparably important to appreciate.

In some instances, an unexpected combination of findings may be particularly helpful in identifying a xenobiotic or a combination of xenobiotics. For example, a dissociation between such typically paired changes as an increase in pulse with a decrease in blood pressure (cyclic antidepressants or phenothiazines), or the presentation of a decrease in pulse with an increase in blood pressure (ergot alkaloids) may be extremely helpful in diagnosing a toxic etiology. The use of these unexpected or atypical clinical findings is demonstrated in [Chap. 17](#).

BLOOD PRESSURE

Xenobiotics cause hypotension by four major mechanisms: decreased peripheral vascular resistance, decreased myocardial contractility, dysrhythmias, and depletion of intravascular volume. Many xenobiotics can initially cause orthostatic hypotension without marked supine hypotension, and any xenobiotic that affects autonomic control of the heart or peripheral capacitance vessels may lead to orthostatic hypotension ([Table 3–3](#)). Hypertension from xenobiotics may be caused by CNS sympathetic overactivity, increased myocardial contractility or increased peripheral vascular resistance, or a combination of these.

TABLE 3–3. Common Xenobiotics That Affect the Blood Pressure^a

<i>Hypotension</i>	<i>Hypertension</i>
α_1 -Adrenergic antagonists	α_1 -Adrenergic agonists
α_2 -Adrenergic agonists	α_2 -Adrenergic antagonists
β -Adrenergic antagonists	Ergot alkaloids
Angiotensin-converting enzyme inhibitors	Lead (chronic)
Angiotensin receptor blockers	Monoamine oxidase inhibitors (overdose early and drug–food interaction)
Antidysrhythmics	Nicotine (early)
Calcium channel blockers	Phencyclidine
Cyanide	Sympathomimetics
Cyclic antidepressants	
Ethanol and other alcohols	
Iron	
Methylxanthines	
Nitrates and nitrites	
Nitroprusside	
Opioids	
Phenothiazines	
Phosphodiesterase-5 inhibitors	
Sedative–hypnotics	

^aChapter 17 lists additional xenobiotics that affect hemodynamic function.

Blood pressure and pulse rate may vary significantly as a result of changes in receptor responsiveness, degree of physical fitness, and degree of atherosclerosis. Changing patterns of blood pressure often assist in the diagnostic evaluation: overdose with a monoamine oxidase inhibitor (MAOI) characteristically causes an initial normal blood pressure, to be followed by hypertension, which, in turn, may be followed abruptly by severe hypotension ([Chap. 73](#)).

PULSE RATE

Extremely useful clinical information can be obtained by evaluating the pulse rate ([Table 3–4](#) and [Chap. 17](#)). Although the carotid artery is usually easily palpable, for reasons of both safety and reliability, the brachial artery is preferred in infants and in adults older than 60 years. The normal heart rate for adults was defined by consensus more than 50 years ago as a regular rate greater than 60 beats/min and less than 100 beats/min. More recent studies^{7,8} suggest that 95% of the population

has bradycardia and tachycardia thresholds of 50 beats/min and 90 beats/min, respectively. In our text, we have chosen to retain the consensus values.

TABLE 3–4. Common Xenobiotics That Affect the Pulse^a

<i>Bradycardia</i>	<i>Tachycardia</i>
α ₂ -Adrenergic agonists	Anticholinergics
β-Adrenergic antagonists	Antipsychotics
Baclofen	Cyclic antidepressants
Calcium channel blockers	Disulfiram-ethanol interaction
Cardioactive steroids	Ethanol and sedative-hypnotic withdrawal
Ciguatoxin	Iron
Ergot alkaloids	Methylxanthines
γ-Hydroxybutyric acid	Phencyclidine
Opioids	Sympathomimetics
Organic phosphorus compounds	Thyroid hormone
	Yohimbine

^aChapter 17 lists additional xenobiotics that affect the heart rate.

Because pulse rate is the net result of a balance between sympathetic (adrenergic) and parasympathetic (muscarinic and nicotinic) tone, many xenobiotics that exert therapeutic or toxic effects or cause pain syndromes, hyperthermia, or volume depletion also affect the pulse rate. With respect to temperature, there is a direct correlation between pulse rate and temperature in that pulse rate increases approximately 8 beats/min for each 1.8°F (1°C) elevation in temperature.⁴

The inability to differentiate easily between sympathomimetic and anticholinergic xenobiotic effects by vital signs alone illustrates the principle that no single vital sign abnormality can definitively establish a toxicologic diagnosis. In trying to differentiate between a sympathomimetic and anticholinergic toxic syndrome, it should be understood that although tachycardia commonly results from both sympathomimetic and anticholinergic xenobiotics, when tachycardia is accompanied by diaphoresis or increased bowel sounds, adrenergic toxicity is suggested, but when tachycardia is accompanied by decreased sweating, absent bowel sounds, and urinary retention, anticholinergic toxicity is likely.

RESPIRATIONS

Establishment of an airway and evaluation of respiratory status are the initial priorities in patient stabilization. Although respirations are typically assessed initially for rate alone, careful observation of the depth and pattern is essential (Table 3–5) for establishing the etiology of a systemic illness or toxicity.¹ Unfortunately, very few investigators have actually measured the respiratory rate in large populations of normal people, let alone in ED patients. Two papers^{2,3} investigating respiratory rates in ED patients differ substantially in their determinations of normal ranges from the remainder of the literature. The combined results of these investigations suggest “normal” respiratory rates are 16 to 24 breaths/min in adults with more rapid rates that are inversely related to age in children.

TABLE 3–5. Common Xenobiotics That Affect Respiration^a

<i>Bradypnea</i>	<i>Tachypnea</i>
α_2 -Adrenergic agonists	Cyanide
Botulinum toxin	Dinitrophenol and congeners
Elapidae venom	Epinephrine
Ethanol and other alcohols	Ethylene glycol
γ -Hydroxybutyric acid	Hydrogen sulfide
Neuromuscular blockers	Methanol
Opioids	Methemoglobin producers
Organic phosphorus compounds	Methylxanthines
Sedative-hypnotics	Nicotine (early)
	Pulmonary irritants
	Salicylates
	Sympathomimetics

^aChapter 29 lists additional xenobiotics affecting respiratory rate.

The term hyperventilation may mean tachypnea (an increase in ventilatory rate), hyperpnea (an increase in tidal volume), or both ([Chap. 29](#)). When hyperventilation results solely or predominantly from hyperpnea, clinicians may miss this important finding entirely, instead erroneously describing such a hyperventilating patient as normally ventilating or even hypoventilating if bradypnea is also present. The ventilatory status of the patient must be viewed in the context of the patient's physiologic condition.

Hyperventilation may result from the direct effect of a CNS stimulant, such as the direct effect of salicylates, on the brainstem. However, salicylate poisoning characteristically produces hyperventilation by tachypnea, but it also produces hyperpnea with or without tachypnea. Pulmonary injury from any source, including aspiration of gastric contents, may lead to hypoxemia with a resultant tachypnea. Later, tachypnea may change to bradypnea, hypopnea (shallow breathing), or both. Bradypnea may occur when a CNS depressant acts on the brainstem. A progression from fast to slow breathing may also occur in a patient exposed to increasing concentrations of cyanide or carbon monoxide.

TEMPERATURE

Temperature evaluation and control are critical. However, temperature assessment can be done only if safe and reliable equipment is used. The risks of inaccuracy are substantial when an oral temperature is taken in a tachypneic patient, an axillary temperature or a temporal artery temperature is taken in any patient (especially those found outdoors), or a tympanic temperature is taken in a patient with cerumen impaction. Obtaining rectal temperatures using a nonglass probe is essential for safe and accurate temperature determinations in agitated individuals and is considered the standard method of temperature determination in this text.

The core temperature or deep internal temperature (T) is relatively stable ($98.6^\circ \pm 1.08^\circ\text{F}$; $37^\circ \pm 0.6^\circ\text{C}$) under normal physiologic circumstances. Hypothermia ($T < 95^\circ\text{F}$; $< 35^\circ\text{C}$) and hyperthermia ($T > 100.4^\circ\text{F}$; $> 38^\circ\text{C}$) are common manifestations of toxicity. Severe or significant hypothermia and hyperthermia, unless immediately recognized and managed appropriately, may result in grave complications and inappropriate or inadequate resuscitative efforts. Life-threatening hyperthermia ($T > 106^\circ\text{F}$; $> 41.1^\circ\text{C}$) from any cause may lead to extensive rhabdomyolysis, myoglobinuric kidney failure, and direct liver and brain injury and must therefore be identified and corrected immediately.

Hyperthermia may result from a distinct neurologic response to a signal demanding thermal “upregulation.” This signal can be from internal generation of heat beyond the capacity of the body to cool, such as occurs in association with agitation or mitochondrial uncoupling, or from an externally imposed physical or environmental factor, such as the environmental conditions causing heat stroke or the excessive swaddling in clothing causing hyperthermia in infants. Fever, or pyrexia, is hyperthermia caused by an elevation in the hypothalamic thermoregulatory setpoint.

Regardless of etiology, core temperatures higher than 106°F (41.1°C) are extremely rare unless normal feedback mechanisms are overwhelmed. Hyperthermia of this extreme nature is usually attributed to environmental heat stroke; extreme psychomotor agitation; or xenobiotic-related temperature disturbances such as malignant hyperthermia, serotonin toxicity, or the neuroleptic malignant syndrome.

A common xenobiotic-related hyperthermia pattern that frequently occurs in the ED is defervescence after an acute temperature elevation resulting from agitation or a grand mal seizure. [Table 3–6](#) is a representative list of xenobiotics that affect body temperature. ([Chapter 30](#) provides greater detail.)

TABLE 3–6. Common Xenobiotics^a

<i>Hyperthermia</i>	<i>Hypothermia</i>
Anticholinergics	α_2 -Adrenergic agonists
Chlorophenoxy herbicides	Carbon monoxide
Dinitrophenol and congeners	Ethanol
Malignant hyperthermia	γ -Hydroxybutyric acid
Monoamine oxidase inhibitors	Hypoglycemics
Neuroleptic malignant syndrome	Opioids
Phencyclidine	Sedative–hypnotics
Salicylates	Thiamine deficiency
Sedative–hypnotic or ethanol withdrawal	
Serotonin toxicity	
Sympathomimetics	
Thyroid hormone	

^aChapter 30 lists additional xenobiotics that affect temperature.

Hypothermia is probably less of an immediate threat to life than hyperthermia, but it requires rapid appreciation, accurate diagnosis, and skilled management. Hypothermia impairs the metabolism of many xenobiotics, leading to unpredictable delayed and/or prolonged toxicologic effects when the patient is warmed. Many xenobiotics that lead to an alteration of mental status place patients at great risk for becoming hypothermic from exposure to cold climates. Most important, a hypothermic patient should never be declared dead without both an extensive assessment and a full resuscitative effort of adequate duration, taking into consideration the difficulties in resuscitating cold but living patients. This is true whenever the body temperature remains less than 95°F (35°C) ([Chap. 30](#)).

SUMMARY

- Early, accurate determinations followed by serial monitoring of the vital signs are as essential in medical toxicology as in any other type of emergency or critical care medicine.
- Careful observation of the vital signs helps to determine appropriate therapeutic interventions and guide the clinician in making necessary adjustments to initial and subsequent therapeutic interventions.
- When pathognomonic clinical and laboratory findings are combined with accurate initial and sometimes changing vital signs, a toxic syndrome may become evident, which will aid in both general supportive and specific antidotal treatment.
- Correct identification of toxic syndromes will also guide further diagnostic testing.

4 PRINCIPLES OF MANAGING THE ACUTELY POISONED OR OVERDOSED PATIENT

Robert S. Hoffman, Mary Ann Howland, Neal A. Lewin, Lewis S. Nelson, and Lewis R. Goldfrank

OVERVIEW

For over 5 decades, medical toxicologists and poison information specialists have used a clinical approach to poisoned or overdosed patients that emphasizes treating the patient rather than treating the poison.¹ Too often in the past, patients were initially all but neglected while attention was focused on the ingredients listed on the containers of the product(s) to which they presumably were exposed. Although the astute clinician must always be prepared to administer a specific antidote immediately in instances when nothing else will save a patient, such as cyanide poisoning, all poisoned or overdosed patients will benefit from an organized, rapid clinical management plan (Fig. 4–1).

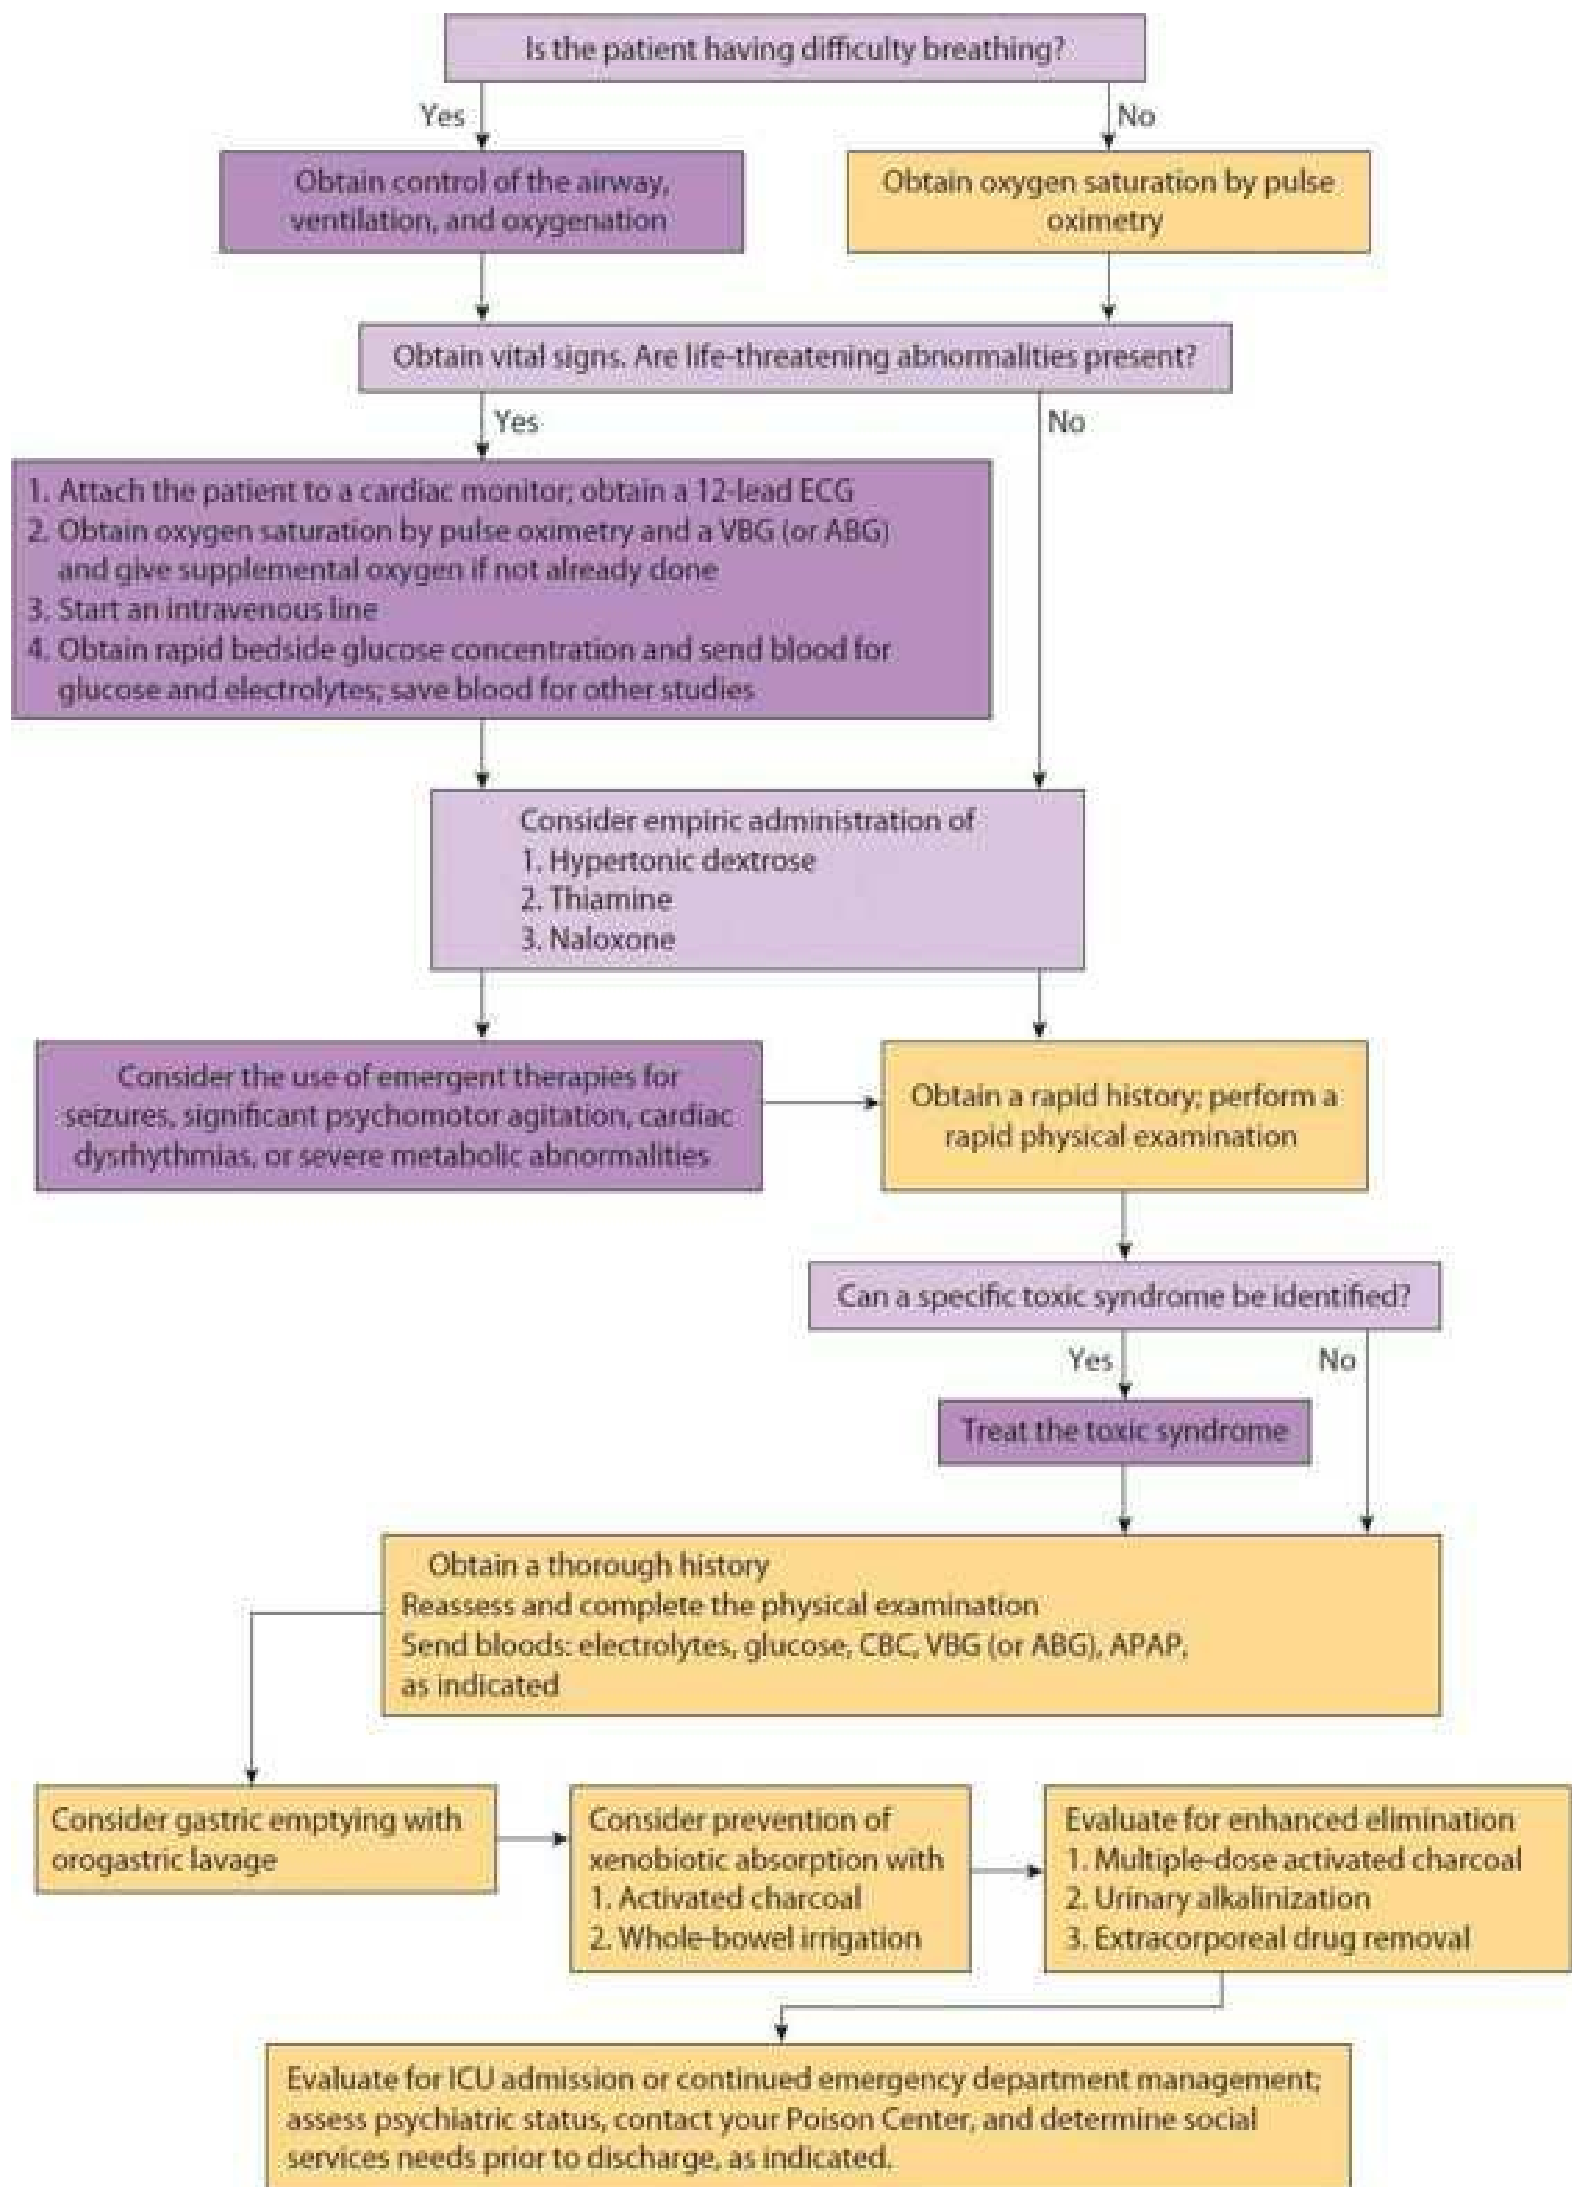

FIGURE 4–1. This algorithm is a basic guide to the management of poisoned patients. A more detailed description of the steps in management may be found in the accompanying text. This algorithm is only a guide to actual management, which must, of course, consider the patient’s clinical status. ABG = arterial blood gas; CBC = complete blood count; ICU = intensive care unit; VBG = venous blood gas.

Over the past 4 decades, some basic tenets and long-held beliefs regarding the initial therapeutic interventions in toxicologic management have been questioned and subjected to an “evidence-based” analysis. For example, in the mid-1970s, most medical toxicologists began to advocate a standardized approach to a comatose and possibly overdosed adult patient, typically calling for the intravenous (IV) administration of 50 mL of dextrose 50% in water (D₅₀W), 100 mg of thiamine, and 2 mg of naloxone along with 100% oxygen at high flow rates. The rationale for this approach was to compensate for the previously idiosyncratic style of overdose management encountered in different health care settings and for the unfortunate likelihood that omitting any one of these measures at the time that care was initiated in the emergency department (ED) would result in omitting it altogether. It was not unusual then to discover from a laboratory chemistry report more than one hour after a supposedly overdosed comatose patient had arrived in the ED that the initial blood glucose was 30 or 40 mg/dL—a critical delay in the management of unsuspected and consequently untreated hypoglycemic coma. Today, however, with the widespread availability of accurate rapid bedside testing for capillary glucose, pulse oximetry for oxygen saturation, and end-tidal CO₂ monitors coupled with a much greater appreciation by all physicians of what needs to be done for each suspected overdose patient, clinicians can safely provide a more rational, individualized approach to determine the need for, and in some instances more precise amounts of, dextrose, thiamine, naloxone, and oxygen.

A second major approach to providing more rational individualized early treatment for toxicologic emergencies involves a closer examination of the actual risks and benefits of various gastrointestinal (GI) emptying interventions. Appreciation of the potential for significant adverse effects associated with all types of GI emptying interventions and recognition of the absence of clear evidence-based support of efficacy have led to abandoning of syrup of ipecac-induced emesis, an almost complete elimination of orogastric lavage, and a significant reduction in the routine use of activated charcoal (AC). The value of whole-bowel irrigation (WBI) with polyethylene glycol electrolyte solution (PEG-ELS) appears to be much more specific and limited than originally thought, and some of the limitations and (uncommon) adverse effects of AC are now more widely recognized.

Similarly, interventions to eliminate absorbed xenobiotics from the body are now much more narrowly defined or, in some cases, abandoned. Multiple-dose activated charcoal (MDAC) is useful for select but not all xenobiotics. Ion trapping in the urine is only beneficial, achievable, and relatively safe when the urine can be maximally alkalinized after a significant salicylate or phenobarbital poisoning. Finally, the roles of hemodialysis, hemoperfusion, and other extracorporeal techniques are now much more specifically defined.² With the foregoing in mind, this chapter represents our current efforts to formulate a logical and effective approach to managing a patient with probable or actual toxic exposure.

Table 4–1 provides a recommended stock list of antidotes and therapeutics for the treatment of poisoned or overdosed patients.

TABLE 4–1. Antidotes and Therapeutics for the Treatment of Poisonings and Overdoses^a

Therapeutics ^a	Uses	Therapeutics ^a	Uses
Activated charcoal (p. 97)	Adjuvant antibiotics in the GI tract	Hydroxocobalamin (Cyanokit) (p. 1618)	Cyanide
Antivenom (<i>Centruroides</i> spp) (p. 1484)	Scorpion envenomation	Insulin (p. 851)	β -Adrenergic antagonists, CCBs, hyperglycemia
Antivenom (<i>Crotalinae</i>) (p. 1547)	Crotaline snake envenomations	Iodide (SSKI) (p. 1713)	Radioactive iodine (I^{131})
Antivenom (<i>Elopidre</i>) (p. 1547)	Coral snake envenomations	Ipecac, syrup of (p. 84)	Induces emesis
Antivenom (<i>Lutrodoctus mactans</i>) (p. 1489)	Black widow spider envenomations	Magnesium sulfate or magnesium citrate (p. 104)	Induces catharsis
Antivenom (<i>Synanceja</i> spp) (p. 1494)	Stonefish envenomation	Magnesium sulfate injection (p. 258)	Cardioactive steroids, hydrofluoric acid, hypomagnesemia, ethanol withdrawal, torsade de pointes
Atropine (p. 1425)	Bradycardias, cholinesterase inhibitors (organic phosphorus compounds, physostigmine) muscarinic mushrooms (<i>Clitocybe</i> , <i>Inocybe</i>) ingestions	Methylene blue (1% solution) (p. 1631)	Methemoglobinemia
Benzodiazepines (p. 1069)	Seizures, agitation, stimulants, ethanol and sedative-hypnotic withdrawal, cocaine, chloroquine, organic phosphorus compounds	N-acetylcysteine (Acetadote) (p. 465)	APAP and other causes of hepatotoxicity
Botulinum antitoxin (ABE-trivalent) (p. 559)	Botulism	Naloxone hydrochloride (Narcan) (p. 510)	Opioids, dantrolene
Calcium chloride, calcium gluconate (p. 1330)	Fluoride, hydrofluoric acid, ethylene glycol, CCBs, hypomagnesemia, β -adrenergic antagonists	Norepinephrine (Levophed) (p. 978)	Hypotension (preferred for cyclic antidepressants)
L-Carnitine (p. 657)	Valproic acid; hyperammonemia	Octreotide (Sandostatin) (p. 738)	Insulin secretagogues induced hypoglycemia
Cyanide kit (nitrites, p. 1612; sodium thiosulfate, p. 1615)	Cyanide	Oxygen (Hyperbaric) (p. 1594)	Carbon monoxide, cyanide, hydrogen sulfide
Cyproheptadine (p. 1023)	Serotonin toxicity	α -Penicillamine (Cuprimine) (p. 1215)	Copper
Dantrolene (p. 955)	Malignant hyperthermia	Phenobarbital (p. 1005)	Seizures, agitation, stimulants, ethanol and sedative-hypnotic withdrawal
Deferoxamine (Desferal) (p. 623)	Iron	Phentolamine (p. 1058)	Vasoconstriction: cocaine, MAOI interactions, epinephrine, and ergot alkaloids
Dextrose in water (50% adults; 20% pediatrics; 10% neonates) (p. 732)	Hypoglycemia	Physostigmine (Antilirium) (p. 905)	Anticholinergics
Digoxin-specific antibody fragments (p. 904)	Cardioactive steroids	Polyethylene glycol electrolyte solution (p. 104)	Decontamination
Dimercaprit (BAL, British anti-Lewisite) (p. 1181)	Arsenic, mercury, gold, lead	Pralidoxime chloride (2-PAM-chloride; Protopam) (p. 1429)	Acetylcholinesterase inhibitors (organic phosphorus compounds and carbamates)
Diphenhydramine (p. 663)	Dystonic reactions, allergic reactions	Protamine (p. 839)	Heparin anticoagulation
DTPA (p. 1717)	Radioactive isotopes	Prussian blue (Radiogardase) (p. 1283)	Thallium, cesium
Edetate calcium disodium (calcium disodium versenate, CaNa ₂ EDTA) (p. 1241)	Lead, other selected metals	Pyridoxine (vitamin B ₆) (p. 797)	Isoniazid, ethylene glycol, gyromitrin-containing mushrooms
Ethanol (p. 1369)	Methanol, ethylene glycol	Silibinin (p. 1515)	Amatoxin mushroom poisoning
Fat emulsion (Intralipid 20%) (p. 933)	Cardiac arrest; local anesthetics	Sodium bicarbonate (p. 528)	Ethylene glycol, methanol, salicylates, cyclic antidepressants, methotrexate, phenobarbital, quinidine, chlorpropamide, Class I antidysrhythmics, chlorophenyl herbicides
Flumazenil (Romazicon) (p. 1013)	Benzodiazepines	Starch (p. 1298)	Iodine
Folic acid (Leucovorin) (p. 693)	Methotrexate, methanol	Succimer (Chemet) (p. 1235)	Lead, mercury, arsenic
Fomepizole (Antizole) (p. 1364)	Ethylene glycol, methanol	Thiamine (vitamin B ₃) (p. 1094)	Thiamine deficiency, ethylene glycol, chronic ethanol consumption ("alcoholism")
Glucagon (p. 870)	β -Adrenergic antagonists, CCBs	Vitamin K ₁ (Aquamephyton) (p. 836)	Warfarin or rodenticide anticoagulants
Glucarpitase (p. 698)	Methotrexate	Whole-bowel irrigation (p. 104)	Induces catharsis

Each emergency department should have the vast majority of these antidotes immediately available; some of these antidotes may be stored in the pharmacy, and others may be available from the Centers for Disease Control and Prevention, but the precise mechanism for locating each one must be known by each staff member. ^aA detailed analysis of each of these agents is found in the Antidotes in Depth section on the page cited to the right of each antidote or therapeutic listed.

CCB = calcium channel blockers; DTPA = diethylenetriaminepentaacetic acid; DTPA = ethylenediamine tetraacetic acid; GI = gastrointestinal; MAOI = monoamine oxidase inhibitor; SSKI = saturated solution of potassium iodide.

MANAGING ACUTELY POISONED OR OVERDOSED PATIENTS

Rarely, if ever, are all of the circumstances involving a poisoned patient known. The history may be incomplete, unreliable, or unobtainable; multiple xenobiotics may be involved; and even when a xenobiotic etiology is identified, it may not be easy to determine whether the problem is an overdose, an allergic or idiosyncratic reaction, or a drug–drug interaction. Similarly, it is sometimes difficult or impossible to differentiate between the adverse effects of a correct dose of medication and the consequences of a deliberate or unintentional overdose. The patient’s presenting signs and symptoms may force an intervention at a time when there is almost no information available about the etiology of the patient’s condition (Table 4–2), and as a result, therapeutics must be thoughtfully chosen empirically to treat or diagnose a condition without exacerbating the situation.

TABLE 4–2. Clinical and Laboratory Findings in Poisoning and Overdose

Agitation	Anticholinergics, ^a hypoglycemia, phencyclidine, sympathomimetics, ^b withdrawal from ethanol and sedative-hypnotics
Alopecia	Alkylating agents, radiation, selenium, thallium
Ataxia	Benzodiazepines, carbamazepine, carbon monoxide, ethanol, hypoglycemia, lithium, mercury, nitrous oxide, phenytoin
Blindness or decreased visual acuity	Caustics (direct), cisplatin, cocaine, mercury, methanol, quinine, thallium
Blue skin	Amiodarone, FD&C #1 dye, methemoglobinemia, silver
Constipation	Anticholinergics, ^a botulism, lead, opioids, thallium (severe)
Deafness, tinnitus	Aminoglycosides, cisplatin, loop diuretics, metals, quinine, salicylates
Diaphoresis	Amphetamines, cholinergics, ^c hypoglycemia, opioid withdrawal, salicylates, serotonin syndrome, sympathomimetics, ^b withdrawal from ethanol and sedative-hypnotics
Diarrhea	Arsenic and other metals, boric acid (blue-green), botanical irritants, cathartics, cholinergics, ^c colchicine, iron, lithium, opioid withdrawal, radiation
Dysesthesias, paresthesias	Acrylamide, arsenic, ciguatera, cocaine, colchicine, thallium
Gum discoloration	Arsenic, bismuth, hypervitaminosis A, lead, mercury
Hallucination	Anticholinergics, ^a dopamine agonists, ergot alkaloids, ethanol, ethanol and sedative-hypnotic withdrawal, LSD, phencyclidine, sympathomimetics, ^b tryptamines
Headache	Carbon monoxide, hypoglycemia, monoamine oxidase inhibitor–food interaction (hypertensive crisis), serotonin toxicity
Metabolic acidosis (elevated anion gap)	Methanol, uremia, ketoacidosis (diabetic, starvation, alcoholic), paraldehyde, phenformin, metformin, iron, isoniazid, lactic acidosis, cyanide, protease inhibitors, ethylene glycol, salicylates, toluene
Miosis	Cholinergics, ^c clonidine, opioids, phencyclidine, phenothiazines
Mydriasis	Anticholinergics, ^a botulism, opioid withdrawal, sympathomimetics ^b
Nystagmus	Barbiturates, carbamazepine, carbon monoxide, ethanol, lithium, monoamine oxidase inhibitors, phencyclidine, phenytoin, quinine
Purpura	Anticoagulant rodenticides, clopidogrel, corticosteroids, heparin, pit viper venom, quinine, salicylates, warfarin
Radiopaque ingestion	Arsenic, halogenated hydrocarbons, metals (eg, iron, lead)
Red skin	Anticholinergics, ^a boric acid, disulfiram, hydroxocobalamin, scambroid, vancomycin
Rhabdomyolysis	Carbon monoxide, doxylamine, HMG-CoA reductase inhibitors, sympathomimetics, ^b <i>Tricholoma equestre</i> mushrooms
Salivation	Arsenic, caustics, cholinergics, ^c ketamine, mercury, phencyclidine, strychnine
Seizures	Bupropion, camphor, carbon monoxide, cyclic antidepressants, Gyromitra mushrooms, hypoglycemia, isoniazid, methylxanthines, ethanol and sedative-hypnotic withdrawal
Tremor	Antipsychotics, arsenic, carbon monoxide, cholinergics, ^c ethanol, lithium, mercury, methyl bromide, sympathomimetics, ^b thyroid replacement
Weakness	Botulism, diuretics, magnesium, paralytic shellfish, steroids, toluene
Yellow skin	APAP (late), pyrrolizidine alkaloids, β carotene, amatoxin mushrooms, dinitrophenol

^aAnticholinergics, including antihistamines, atropine, cyclic antidepressants, and scopolamine. ^bSympathomimetics, including adrenergic agonists, amphetamines, cocaine, and epinephrine. ^cCholinergics, including muscarinic mushrooms, organic phosphorus compounds, and carbamates, including select Alzheimer's disease drugs and physostigmine, and pilocarpine and other direct-acting cholinergics.

HMG-CoA = 3-hydroxy-3-methyl-glutaryl-CoA; LSD = lysergic acid diethylamide; MAOI = monoamine oxidase inhibitor.

Initial Management of Patients with a Suspected Exposure

Similar to the management of any seriously compromised patient, the clinical approach to the patient potentially exposed to a xenobiotic begins with the recognition and treatment of life-threatening conditions, including airway compromise, breathing difficulties, and circulatory problems such as hemodynamic instability and serious dysrhythmias. After the “ABCs” (airway, breathing, and circulation) have been addressed, the patient’s level of consciousness should be assessed because this helps determine the techniques to be used for further management of the exposure.

Management of Patients with Altered Mental Status

Altered mental status (AMS) is defined as the deviation of a patient's sensorium from normal. Although it is commonly construed as a depression in the patient's level of consciousness, a patient with agitation, delirium, psychosis, and other deviations from normal is also considered to have an AMS. After airway patency is established or secured, an initial bedside assessment should be made regarding the adequacy of breathing. If it is not possible to assess the depth and rate of ventilation, then at least the presence or absence of regular breathing should be determined. In this setting, any irregular or slow breathing pattern should be considered a possible sign of the incipient apnea, requiring ventilation with 100% oxygen by bag–valve–mask followed as soon as possible by endotracheal intubation and mechanical ventilation. Endotracheal intubation may be indicated for some cases of coma resulting from a toxic exposure to ensure and maintain control of the airway and to enable safe performance of procedures to prevent GI absorption or eliminate previously absorbed xenobiotics.

Although in many instances, the widespread availability of pulse oximetry to determine O₂ saturation and end-tidal CO₂ monitors have made arterial blood gas (ABG) analysis less of an immediate priority, these technical advances have not entirely eliminated the importance of blood gas analysis. An ABG determination will more accurately define the adequacy not only of oxygenation (PO₂, O₂ saturation) and ventilation (PCO₂) but may also alert the physician to possible toxic-metabolic etiologies of coma characterized by acid–base disturbances (pH, PCO₂) ([Chap. 19](#)). In addition, carboxyhemoglobin determinations are now available by point-of-care testing, and both carboxyhemoglobin and methemoglobin may be determined on either venous or arterial blood specimens ([Chaps. 125 and 127](#)). In every patient with an AMS, a bedside rapid capillary glucose concentration should be obtained as soon as possible.

After the patient's respiratory status has been assessed and managed appropriately, the strength, rate, and regularity of the pulse should be evaluated, the blood pressure determined, and a rectal temperature obtained. Both an initial 12-lead electrocardiogram (ECG) and continuous rhythm monitoring are essential. Monitoring will alert the clinician to dysrhythmias that are related to toxic exposures either directly or indirectly via hypoxemia or electrolyte imbalance. For example, a 12-lead ECG demonstrating QRS widening and a right axis deviation might indicate a life-threatening exposure to a cyclic antidepressant or another xenobiotic with sodium channel–blocking properties. In these cases, the physician can anticipate such serious sequelae as ventricular tachydysrhythmias, seizures, and cardiac arrest and consider both the early use of specific treatment (antidotes), such as IV sodium bicarbonate, and avoidance of medications, such as procainamide and other class IA and IC antidysrhythmics, which could exacerbate the situation.

Extremes of core body temperature must be addressed early in the evaluation and treatment of a comatose patient. Life-threatening hyperthermia (temperature >106°F; >41.1°C) is usually appreciated when the patient is touched (although the widespread use of gloves as part of universal precautions has made this less apparent than previously). Most individuals with severe hyperthermia, regardless of the etiology, should have their temperatures immediately reduced to about 101.5°F (38.7°C) by sedation if they are agitated or displaying muscle rigidity and by ice water immersion ([Chap. 30](#)). Hypothermia is probably easier to miss than hyperthermia, especially in northern regions during the winter months, when most arriving patients feel cold to the touch. Early recognition of hypothermia, however, helps to avoid administering a variety of medications that may be ineffective until the patient becomes relatively euthermic, which may cause iatrogenic toxicity as a result of a sudden response to xenobiotics previously administered.

For a hypotensive patient with clear lungs and an unknown overdose, a fluid challenge with IV 0.9% sodium chloride or lactated Ringer solution may be started. If the patient remains hypotensive or cannot tolerate fluids, an antidote, a vasopressor, or an inotropic agent may be indicated, as may more invasive monitoring.

At the time that the IV catheter is inserted, blood samples for glucose, electrolytes, blood urea nitrogen (BUN), a complete blood count (CBC), and any indicated toxicologic analyses can be obtained. A pregnancy test should be obtained in any woman with childbearing potential. If the patient has an AMS, there may be a temptation to send blood and urine specimens to identify any central nervous system (CNS) depressants or so-called drugs of abuse in addition to other medications. But the indiscriminate ordering of these tests rarely provides clinically useful information. For the potentially suicidal patient, an APAP concentration should be routinely requested along with tests affecting the management of any specific xenobiotic, such as carbon monoxide, lithium, theophylline, iron, salicylates, and digoxin (or other cardioactive steroids), as suggested by the patient's history, physical examination, or bedside diagnostic tests. In the vast majority of cases, the blood tests that are most useful in diagnosing toxicologic emergencies are not the toxicologic assays but rather the “nontoxicologic” routine metabolic profile tests such as BUN, glucose, electrolytes, and blood gas analysis.

Xenobiotic-related seizures may broadly be divided into three categories: (1) those that respond to standard anticonvulsant treatment (typically using a benzodiazepine); (2) those that either require specific antidotes to control seizure activity or that do not respond consistently to standard anticonvulsant treatment, such as isoniazid-induced seizures requiring pyridoxine administration; and (3) those that may appear to respond to initial treatment with cessation of tonic–clonic activity but that leave the patient exposed to the underlying, unidentified xenobiotic or to continued electrical seizure activity, as is the case with carbon monoxide poisoning and hypoglycemia.

Within the first 5 minutes of managing a patient with an AMS, four therapeutic interventions should be considered, and if indicated, administered:

1. High-flow oxygen (8–10 L/min) to treat a variety of xenobiotic-induced hypoxic conditions
2. Hypertonic dextrose: 0.5–1.0 g/kg of D₅₀W for an adult or a more dilute dextrose solution (D₁₀W or D₂₅W) for a child; the dextrose is administered as an IV bolus to diagnose and treat or exclude hypoglycemia
3. Thiamine (100 mg IV for an adult; usually unnecessary for a child) to prevent or treat Wernicke encephalopathy
4. Naloxone (0.04 mg IV with upward titration) for an adult or child with opioid-induced respiratory compromise

The clinician must consider that hypoglycemia may be the sole or contributing cause of coma even when the patient manifests focal neurologic findings; therefore, dextrose administration should only be omitted when hypoglycemia can be definitely excluded by accurate rapid bedside testing. Also, while examining a patient for clues to the etiology of a presumably toxic-metabolic form of AMS, it is important to search for any indication that trauma may have caused, contributed to, or resulted from the patient's condition. Conversely, the possibility of a concomitant drug ingestion or toxic metabolic disorder in a patient with obvious head trauma should also be considered.

The remainder of the physical examination should be performed rapidly but thoroughly. In addition to evaluating the patient's level of consciousness, the physician should note abnormal posturing (decorticate or decerebrate), abnormal or unilateral withdrawal responses, and pupil size and reactivity. Pinpoint pupils suggest exposure to opioids or organic phosphorus insecticides, and widely dilated pupils suggest anticholinergic or sympathomimetic poisoning. The presence or absence of nystagmus, abnormal reflexes, and any other focal neurologic findings may provide important clues to a structural cause of AMS. For clinicians accustomed to applying the Glasgow Coma Scale (GCS) to all patients with AMS, assigning a score to the overdosed or poisoned patient may provide a useful measure for assessing changes in neurologic status. However, in this situation, the GCS should never be used for prognostic purposes because despite a low GCS score, complete recovery from properly managed toxic-metabolic coma is the rule rather than the exception ([Chap. 24](#)).

Characteristic breath or skin odors may identify the etiology of coma. The fruity odor of ketones on the breath suggests diabetic or alcoholic ketoacidosis but also the possible ingestion of acetone or isopropyl alcohol, which is metabolized to acetone. The pungent, minty odor of oil of wintergreen on the breath or skin suggests methyl salicylate poisoning. The odors of other substances such as cyanide ("bitter almonds"), hydrogen sulfide ("rotten eggs"), and organic phosphorus compounds ("garlic") are described in detail in [Chap. 26](#) and summarized in [Table 26–1](#).

Further Evaluation of All Patients with Suspected Xenobiotic Exposures

Auscultation of breath sounds, particularly after a fluid challenge, helps to diagnose pulmonary edema, acute lung injury, or aspiration pneumonitis when present. Coupled with an abnormal breath odor of hydrocarbons or organic phosphorus compounds, for example, crackles and rhonchi may point to a toxic pulmonary etiology instead of a cardiac etiology; this is important because the administration of certain cardioactive medications may be inappropriate or dangerous in the former circumstances.

Heart murmurs in an injection drug user, especially when accompanied by fever, may indicate bacterial endocarditis. Dysrhythmias may suggest overdoses or inappropriate use of cardioactive xenobiotics, such as digoxin and other cardioactive steroids, β -adrenergic antagonists, calcium channel blockers, and cyclic antidepressants.

The abdominal examination may reveal signs of trauma or alcohol-related hepatic disease. The presence or absence of bowel sounds helps to exclude or to diagnose anticholinergic toxicity and is important in considering whether to manipulate the GI tract in an attempt to remove the toxin. A large palpable bladder may signal urinary retention as a further manifestation of anticholinergic toxicity.

Examination of the extremities might reveal clues to current or former drug use (track marks, skin-popping scars); metal poisoning (Mees lines, arsenical dermatitis); and the presence of cyanosis or edema suggesting preexisting cardiac, pulmonary, or kidney disease ([Chap. 29](#)).

Repeated evaluation of the patient suspected of an overdose is essential for identifying new or developing findings or toxic syndromes and for early identification and treatment of a deteriorating condition. Until the patient is completely recovered or considered no longer at risk for the consequences of a xenobiotic exposure, frequent reassessment must be provided even as the procedures described later are carried out. Toxicologic etiologies of abnormal vital signs and physical findings are summarized in [Tables 3–1 to 3–6](#). Toxic syndromes, sometimes called "toxidromes," are summarized in [Table 3–1](#).

Typically in the management of patients with toxicologic emergencies, there is both a necessity and an opportunity to obtain various diagnostic studies and ancillary tests interspersed with stabilizing the patient's condition, obtaining the history, and performing the physical examination. [Chapters 5, 6, and 16](#) discuss the timing and indications for diagnostic imaging procedures, qualitative and quantitative diagnostic laboratory studies, and the use and interpretation of the ECG in evaluating and managing poisoned or overdosed patients.

The Role of Gastrointestinal Evacuation

A series of highly individualized treatment decisions must now be made. As noted previously and as discussed in detail in [Chap. 8](#), the decision to evacuate the GI tract or administer AC can no longer be considered standard or routine toxicologic

care for most patients. Instead, the decision should be based on the type of ingestion, estimated quantity and size of pill or tablet, time since ingestion, concurrent ingestions, ancillary medical conditions, and age and size of the patient. The indications, contraindications, and procedures for performing orogastric lavage and for administering WBI, AC, MDAC, and cathartics are listed in [Tables 8–1 through 8–7](#) and are discussed in [Chap. 8](#) and in the specific Antidotes in Depth sections immediately following [Chap. 8](#).

Eliminating Absorbed Xenobiotics from the Body

After deciding whether or not an intervention to try to prevent absorption of a xenobiotic is indicated, the clinician must next consider the applicability of techniques available to eliminate xenobiotics already absorbed. Detailed discussions of the indications for and techniques of manipulating urinary pH (ion trapping), diuresis, hemodialysis, hemoperfusion, hemofiltration, and exchange transfusion are found in [Chap. 10](#). Briefly, patients who may benefit from these procedures are those who have systemically absorbed xenobiotics amenable to one of these techniques and whose clinical conditions are both serious (or potentially serious) and unresponsive to supportive care or whose physiologic route of elimination (liver–feces, kidney–urine) is impaired.

Alkalinization of the urinary pH for acidic xenobiotics has only limited applicability. Commonly, sodium bicarbonate can be used to alkalinize the urine (as well as the blood) and enhance salicylate elimination (other xenobiotics are discussed in [Chap. 10](#)), and sodium bicarbonate also prevents toxicity from methotrexate (Antidotes in Depth: A5). Acidifying the urine to hasten the elimination of alkaline substances is difficult to accomplish, probably useless, and possibly dangerous and therefore has no role in poison management. Forced diuresis also has no indication and may endanger the patient by causing pulmonary or cerebral edema.

If extracorporeal elimination is contemplated, hemodialysis should be considered for overdoses of salicylates, methanol, ethylene glycol, lithium, valproic acid, and xenobiotics that are both dialyzable and cause fluid and electrolyte problems. If available, hemoperfusion or high-flux hemodialysis should be considered for overdoses of theophylline, phenobarbital, and carbamazepine (although rarely, if ever, for the last two). When hemoperfusion is the method of choice (as for a theophylline overdose) but not available, hemodialysis is a logical, effective alternative and certainly preferable to delaying treatment until hemoperfusion becomes available. Peritoneal dialysis is too ineffective to be of practical utility, and hemodiafiltration is not as efficacious as hemodialysis or hemoperfusion, although it may play a role between multiple runs of dialysis or in hemodynamically compromised patients who cannot tolerate hemodialysis. In theory, both hemodialysis and hemoperfusion in series may be useful for a very few life-threatening overdoses such as thallium or salicylates. Plasmapheresis and exchange transfusion are used to eliminate xenobiotics with large molecular weights that are not dialyzable ([Chap. 10](#)).

AVOIDING PITFALLS

The history alone may not be a reliable indicator of which patients require naloxone, hypertonic dextrose, thiamine, and oxygen. Instead, these therapies should be considered (unless specifically contraindicated) only after a clinical assessment for all patients with AMS. The physical examination should be used to guide the use of naloxone. If dextrose or naloxone is indicated, sufficient amounts should be administered to exclude or treat hypoglycemia or opioid toxicity, respectively.

In a patient with a suspected but unknown overdose, the use of vasopressors should be avoided in the initial management of hypotension before administering fluids or assessing filling pressures.

Attributing an AMS to alcohol because of its odor on a patient's breath is potentially dangerous and misleading. Small amounts of alcohol and its congeners generally produce the same breath odor as do intoxicating amounts. Conversely, even when an extremely high blood ethanol concentration is confirmed by the laboratory, it is dangerous to ignore other possible causes of an AMS. Because individuals with chronic alcoholism may be awake and seemingly alert with ethanol concentrations in excess of 500 mg/dL, a concentration that would result in coma and possibly apnea and death in a nontolerant person, finding a high ethanol concentration does not eliminate the need for further search into the cause of a depressed level of consciousness.

The metabolism of ethanol is fairly constant at 15 to 30 mg/dL/h. Therefore, as a general rule, regardless of the initial blood alcohol concentration, a presumably “inebriated” comatose patient who is still unarousable 3 to 4 hours after initial assessment should be considered to have head trauma, a cerebrovascular accident, CNS infection, or another toxic-metabolic etiology for the alteration in consciousness, until proven otherwise. Careful neurologic evaluation of the completely undressed patient supplemented by a head computed tomography scan or a lumbar puncture is frequently indicated in such cases. This is especially important in dealing with a seemingly “intoxicated” patient who appears to have only a minor bruise because the early treatment of a subdural or epidural hematoma or subarachnoid hemorrhage is critical to a successful outcome.

ADDITIONAL CONSIDERATIONS IN MANAGING PATIENTS WITH A

NORMAL MENTAL STATUS

As in the case of the patient with AMS, vital signs must be obtained and recorded. Initially, an assumption may have been made that the patient was breathing adequately, and if the patient is alert, talking, and in no respiratory distress, all that remains to document are the respiratory rate and rhythm. Because the patient is alert, additional history should be obtained, keeping in mind that information regarding the number and types of xenobiotics ingested, time elapsed, prior vomiting, and other critical information may be unreliable, depending in part on whether the ingestion was intentional or unintentional.

When indicated for the potential benefit of the patient, another history should be privately and independently obtained from a friend or relative after the patient has been initially stabilized. Recent emphasis on compliance with the federal Health Insurance Portability and Accountability Act (HIPAA) may inappropriately discourage clinicians from attempting to obtain information necessary to evaluate and treat patients. Obtaining such information from a friend or relative without unnecessarily giving that person information about the patient may be the key to successfully helping such a patient without violating confidentiality.

Speaking to a friend or relative of the patient may provide an opportunity to learn useful and reliable information regarding the ingestion, the patient's frame of mind, a history of previous ingestions, and the type of support that is available if the patient is discharged from the ED. At times, it may be essential to initially separate the patient from any relatives or friends to obtain greater cooperation from the patient and avoid violating confidentiality and because their anxiety may interfere with therapy. Even if the history obtained from a patient with an overdose proves to be unreliable, it may nevertheless provide clues to an overlooked possibility of a second ingestant or reveal the patient's mental and emotional condition. As is often true of the history, physical examination, or laboratory assessment in other clinical situations, the information obtained may confirm but never exclude possible causes.

At this point in the management of a conscious patient, a focused physical examination should be performed, concentrating on the pulmonary, cardiac, and abdominal examinations. A neurologic survey should emphasize reflexes and any focal findings.

APPROACHING PATIENTS WITH INTENTIONAL EXPOSURES

Initial efforts at establishing rapport with the patient by indicating to the patient concern about the problems that led to the ingestion and the availability of help after the xenobiotic is removed (if such procedures are planned) often facilitates management. If GI decontamination is deemed necessary, the reason for and nature of the procedure should be clearly explained to the patient together with reassurance that after the procedure is completed, there will be ample time to discuss related problems and provide additional care. These considerations are especially important in managing the patient with an intentional overdose who may be seeking psychiatric help or emotional support. In deciding on the necessity of GI decontamination, it is important to consider that a resistant patient may transform a procedure of only potential value into one with predictable adverse consequences.

SPECIAL CONSIDERATIONS FOR MANAGING PREGNANT PATIENTS

In general, a successful outcome for both the mother and fetus depends on optimum management of the mother, and proven effective treatment for a potentially serious toxic exposure to the mother should never be withheld based on theoretical concerns regarding the fetus ([Chap. 31](#)).

Physiologic Factors

A pregnant woman's total blood volume and cardiac output are elevated through the second trimester and into the later stages of the third trimester. This means that signs of hypoperfusion and hypotension manifest later than they would in a woman who is not pregnant, and when they do, uterine blood flow may already be compromised. For these reasons, the possibility of hypotension in a pregnant woman must be more aggressively sought and, if found, more rapidly treated. Maintaining the patient in the left-lateral decubitus position helps prevent supine hypotension resulting from impairment of systemic venous return by compression of the inferior vena cava. The left lateral decubitus position is also the preferred position for orogastric lavage if this procedure is deemed necessary.

Because the tidal volume is increased in pregnancy, the baseline PCO₂ will normally be lower by approximately 10 mm Hg. Appropriate adjustment for this effect should be made when interpreting blood gas results.

Use of Antidotes

Limited data are available on the use of antidotes in pregnancy. In general, antidotes should not be used if the indications for use are equivocal. On the other hand, antidotes should not be withheld if their use may reduce potential morbidity and mortality. Risks and benefits of either decision must be considered. For example, reversal of opioid-induced respiratory depression calls for the use of naloxone, but in an opioid-dependent woman, the naloxone can precipitate acute opioid

withdrawal, including uterine contractions and possible induction of labor. Very slow, careful, IV titration starting with 0.04 mg naloxone may be indicated unless apnea is present, cessation of breathing appears imminent, or the PO₂ or O₂ saturation is already compromised. In these instances, naloxone may have to be administered in higher doses (ie, 0.4–2.0 mg) or assisted ventilation provided or a combination of assisted ventilation and small doses of naloxone used.

An APAP overdose is a serious maternal problem when it occurs at any stage of pregnancy, but the fetus is at greatest risk in the third trimester. Although APAP crosses the placenta easily, N-acetylcysteine has somewhat diminished transplacental passage. During the third trimester, when both the mother and the fetus may be at substantial risk from a significant APAP overdose with manifest hepatotoxicity, immediate delivery of a mature or viable fetus may need to be considered.

In contrast to the situation with APAP, the fetal risk from iron poisoning is less than the maternal risk. Because deferoxamine is a large charged molecule with little transplacental transport, deferoxamine should never be withheld out of unwarranted concern for fetal toxicity when indicated to treat the mother.

Carbon monoxide (CO) poisoning is particularly threatening to fetal survival. The normal PO₂ of the fetal blood is approximately 15 to 20 mm Hg. Oxygen delivery to fetal tissues is impaired by the presence of carboxyhemoglobin, which shifts the oxyhemoglobin dissociation curve to the left, potentially compromising an already tenuous balance. For this reason, hyperbaric oxygen is recommended for much lower carboxyhemoglobin concentrations in a pregnant compared with a nonpregnant woman ([Chap. 125](#) and Antidotes in Depth: A38). Early notification of the obstetrician and close cooperation among involved physicians are essential for the best results in all of these instances.

MANAGEMENT OF PATIENTS WITH CUTANEOUS EXPOSURE

The xenobiotics that people are commonly exposed to externally include household cleaning materials; organic phosphorus or carbamate insecticides from crop dusting, gardening, or pest extermination; acids from leaking or exploding batteries; alkalis, such as lye; and lacrimating agents that are used in crowd control. In all of these cases, the principles of management are as follows:

1. Avoid secondary exposures by wearing protective (rubber or plastic) gowns, gloves, and shoe covers. Cases of serious secondary poisoning have occurred in emergency personnel after contact with xenobiotics such as organic phosphorus compounds on the victim's skin or clothing.
2. Remove the patient's clothing, place it in plastic bags, and then seal the bags.
3. Wash the patient with soap and copious amounts of water twice regardless of how much time has elapsed since the exposure.
4. Make no attempt to neutralize an acid with a base or a base with an acid. Further tissue damage may result from the heat generated by this reaction.
5. Avoid using any greases or creams because they will only keep the xenobiotic in close contact with the skin and ultimately make removal more difficult.

[Chapter 18](#) discusses the principles of managing cutaneous exposures.

MANAGEMENT OF PATIENTS WITH OPHTHALMIC EXPOSURES

Although the vast majority of toxicologic emergencies result from ingestion, injection, or inhalation, the eyes are occasionally the routes of systemic absorption or are the organs at risk for ophthalmic exposures. The eyes should be irrigated with the eyelids fully retracted for no less than 20 minutes. To facilitate irrigation, a drop of an anesthetic (eg, proparacaine) in each eye should be used, and the eyelids should be kept open with an eyelid retractor. An adequate irrigation stream may be obtained by running 1 L of 0.9% sodium chloride through regular IV tubing held a few inches from the eye or by using an irrigating lens. Checking the eyelid fornices with pH paper strips is important to ensure adequate irrigation; the pH should normally be 6.5 to 7.6 if accurately tested, although when using paper test strips, the measurement will often be near 8.0. [Chapter 25](#) describes the management of toxic ophthalmic exposures in more detail.

IDENTIFYING PATIENTS WITH NONTOXIC EXPOSURES

There is a risk of needlessly subjecting a patient to potential harm when a patient with a nontoxic exposure is treated aggressively with GI evacuation techniques and other forms of management indicated for serious exposures. More than 40% of exposures reported to poison centers annually are judged to be nontoxic or minimally toxic. The following general guidelines^{3,4} for considering an exposure nontoxic or minimally toxic will assist clinical decision making:

1. Identification of the product and its ingredients is possible.
2. None of the US Consumer Product Safety Commission's "signal words" (CAUTION, WARNING, or DANGER) appear on the product label.

3. The history permits the route(s) of exposure to be determined.
4. The history permits a reliable approximation of the maximum quantity involved with the exposure.
5. Based on the available medical literature and clinical experience, the potential effects related to the exposure are expected to be at most benign and self-limited and do not require referral to a clinician.^{3,4}
6. The patient is asymptomatic or has developed the expected benign self-limited toxicity.

ENSURING OPTIMAL OUTCOME

The best way to ensure an optimal outcome for the patient with a suspected toxic exposure is to apply the principles of basic and advanced life support in conjunction with a planned and stepwise approach, always bearing in mind that a toxicologic etiology or co-etiology for any abnormal conditions necessitates modifying whatever standard approach is brought to the bedside of a severely ill patient. For example, it is extremely important to recognize that xenobiotic-induced dysrhythmias or cardiac instability require alterations in standard protocols that assume a primary cardiac or nontoxicologic etiology ([Chaps. 16 and 17](#)).

Typically, only some of the xenobiotics to which a patient is exposed will ever be confirmed by laboratory analysis. The thoughtful combination of stabilization, general management principles, and specific treatment when indicated will result in successful outcomes in the vast majority of patients with actual or suspected exposures.

SUMMARY

- Patients with a suspected overdose or poisoning and an AMS present some of the most serious initial challenges.
- Conscious patients, asymptomatic patients, and pregnant patients with possible xenobiotic exposures raise additional management issues, as do the victims of toxic cutaneous or ophthalmic exposures.
- One of the most frequent toxicologic emergencies that clinicians must address is a patient with a suspected toxic exposure to an unidentified xenobiotic (medication or substance), sometimes referred to as an unknown overdose.
- Consider not only patients who have an AMS but also those who are suicidal, those who use illicit drugs, and those who are exposed to xenobiotics of which they are unaware.

5 DIAGNOSTIC IMAGING

David T. Schwartz

Diagnostic imaging can play a significant role in the management of many patients with toxicologic emergencies. Radiography can confirm a diagnosis (eg, by visualizing the xenobiotic), assist in therapeutic interventions such as monitoring gastrointestinal (GI) decontamination, and detect complications of the xenobiotic exposure (Table 5–1).¹⁸⁰

TABLE 5–1. Xenobiotics with Diagnostic Imaging Findings

<i>Xenobiotic</i>	<i>Imaging Study*</i>	<i>Finding</i>
Amiodarone	Chest	Phospholipidosis (interstitial and alveolar filling), pulmonary fibrosis
Asbestos	Chest	Interstitial fibrosis (asbestosis), calcified pleural plaques, mesothelioma
Beryllium	Chest	Acute: Airspace filling; chronic: hilar adenopathy
Biphosphonates	Skeletal	Increase bone density, insufficiency fractures femoral shaft
Body packer	Upper GI series or abdominal CT	Ingested packets, ileus, bowel obstruction
Carbon monoxide	Head CT, MRI SPECT, PET	Bilateral basal ganglia lucencies, white matter demyelination, cerebral dysfunction
Gastric ingestion	Enteric contrast	Esophageal perforation or stricture
Chemotherapeutics (busulfan, bleomycin)	Chest	Interstitial pneumonitis
Cholinergics	Chest	Diffuse airspace filling (bronchorrhea)
Cocaine	Chest, abdominal Noncontrast head CT, MRI, TEE, SPECT, PET	Diffuse airspace filling, perianomedastinum, pneumothorax, aortic dissection, perforation SAH, intracerebral hemorrhage, infarction, cerebral dysfunction, dopamine receptor downregulation
Corticosteroids	Skeletal	Avascular necrosis (femoral head)
Ethanol	Chest, Head CT, MRI, SPECT, PET	Dilated cardiomyopathy, aspiration pneumonitis, rib fractures, cortical atrophy, cerebellar atrophy, SDH (head trauma), cerebellar and cortical dysfunction
Fluorosis	Skeletal	Osteodensosis, osteophytosis, ligament calcification
Hydrocarbons (low viscosity)	Chest	Aspiration pneumonitis
Inhaled allergens	Chest	Hypersensitivity pneumonitis
Iron	Abdominal	Radiopaque tablets
Irritant gases	Chest	Diffuse airspace filling
Lead	Skeletal Abdominal	Metaphyseal bands in children (proximal tibia, distal radius), bullets (dissolution near joints); ingested leaded paint chips or other leaded compounds
Manganese	Brain MRI	Basal ganglia and midbrain hyperintensity
Mercury (elemental)	Abdominal, skeletal, or chest	Ingested, injected, or embolic deposits
Metals (Pb, Tl, As)	Abdominal	Ingested xenobiotic
Nitrofurantoin	Chest	Hypersensitivity pneumonitis
Opioids	Chest Abdominal	Acute respiratory distress syndrome Ileus
Phenytoin	Chest	Hilar lymphadenopathy
Procainamide, INH, hydralazine	Chest	Pleural and pericardial effusions (xenobiotic-induced lupus syndrome)
Salicylates	Chest	Acute respiratory distress syndrome
Silica, coal dust	Chest	Interstitial fibrosis, hilar adenopathy (egg-shell calcification)
Thorium dioxide	Abdominal	Hepatic and splenic deposition

*Conventional radiography unless otherwise stated.

CT = computed tomography; INH = isoniazid; MRI = magnetic resonance imaging; PET = positron emission tomography; SAH = subarachnoid hemorrhage; SDH = subdural hematoma; SPECT = single-photon emission tomography.

Conventional radiography is readily available in the emergency department (ED) and is the imaging modality most frequently used in acute patient management. Other imaging modalities are used in certain other toxicologic emergencies, including computed tomography (CT); enteric and intravascular contrast studies; ultrasonography; transesophageal

echocardiography (TEE); magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA); and nuclear scintigraphy, including positron emission tomography (PET) and single-photon emission tomography (SPECT).

VISUALIZING THE XENOBIOTIC

A number of xenobiotics are radiopaque and can potentially be detected by conventional radiography. Radiography is most useful when a substance that is known to be radiopaque is ingested or injected. When the identity of the xenobiotic is unknown, the usefulness of radiography is very limited. When ingested, a radiopaque xenobiotic may be seen on an abdominal radiograph. Injected radiopaque xenobiotics are also amenable to radiographic detection. If the toxic material itself is available for examination, it can be radiographed outside of the body to detect any radiopaque contents (Fig. 105–2).⁷⁶

RADIOACITY

The radiopacity of a xenobiotic is determined by several factors. First, the intrinsic radiopacity of a substance depends on its physical density (g/cm^3) and the atomic numbers of its constituent atoms. Biologic tissues are composed mostly of carbon, hydrogen, and oxygen and have an average atomic number of approximately 6. Substances that are more radiopaque than soft tissues include bone, which contains calcium (atomic number 20), radiocontrast agents containing iodine (atomic number 53) and barium (atomic number 56), iron (atomic number, 26), and lead (atomic number 82). Some xenobiotics have constituent atoms of high atomic number, such as chlorine (atomic number 17), potassium (atomic number 19), and sulfur (atomic number 16) that contribute to their radiopacity.

The thickness of an object also affects its radiopacity. Small particles of a moderately radiopaque xenobiotic are often not visible on a radiograph. Finally, the radiographic appearance of the surrounding area also affects the detectability of an object. A moderately radiopaque tablet is easily seen against a uniform background, but in a patient, overlying bone or bowel gas often obscures the tablet.

ULTRASONOGRAPHY

Compared with conventional radiography, ultrasonography theoretically is a useful tool for detecting ingested xenobiotics because it depends on echogenicity rather than radiopacity for visualization.³³ Solid pills within the fluid-filled stomach may have an appearance similar to gallstones within the gallbladder. In one in vitro study using a water-bath model, virtually all intact pills could be visualized.⁷ The authors were also successful at detecting pills within the stomachs of human volunteers who ingested pills. Nonetheless, reliably finding pills scattered throughout the GI tract, which often contains air and feces that block the ultrasound beam, is a formidable task. Ultrasonography, therefore, has limited clinical practicality.

INGESTION OF AN UNKNOWN XENOBIOTIC

Although a clinical policy issued by the American College of Emergency Physicians in 1995 suggested that an abdominal radiograph should be obtained in unresponsive overdosed patients in an attempt to identify the involved xenobiotic, the role of abdominal radiography in screening a patient who has ingested an unknown xenobiotic is questionable.⁶ The number of potentially ingested xenobiotics that are radiopaque is limited. In addition, the radiographic appearance of an ingested xenobiotic is not sufficiently distinctive to determine its identity (Fig. 5–1).²⁰⁵ However, when ingestion of a radiopaque xenobiotic such as ferrous sulfate tablets or another metal with a high atomic number is suspected, abdominal radiographs are helpful.⁵ In addition, knowledge of potentially radiopaque xenobiotics is useful in suggesting diagnostic possibilities when a radiopaque xenobiotic is discovered on an abdominal radiograph that was obtained for reasons other than suspected xenobiotic ingestion, such as in a patient with abdominal pain (Fig. 5–2).^{179,186}

FIGURE 5–1. Ingestion of an unknown substance. A 46 year-old man presented to the emergency department with a depressed level of consciousness. Because he also complained of abdominal pain and mild diffuse abdominal tenderness, a CT scan of the abdomen was obtained. The CT scan revealed innumerable tablet-shaped densities within the stomach (arrows). The CT finding was suspicious for an overdose of an unknown xenobiotic. Orogastric lavage was attempted, and the patient vomited a large amount of whole navy beans. CT is able to detect small, nearly isodense structures such as these that cannot be seen using conventional radiography. (Used with permission of Dr. Earl J. Reisdorff, MD, Michigan State University, Lansing, MI.)

FIGURE 5–2. Detection of a radiopaque substance on an abdominal radiograph. An abdominal radiograph obtained on a patient with upper abdominal pain revealed radiopaque material throughout the intestinal tract (arrows). Further questioning of the patient revealed that he had been consuming bismuth subsalicylate (Pepto-Bismol) tablets to treat his peptic ulcer (bismuth; atomic number 83). The identification of radiopaque material does not allow determination of the nature of the substance.

Several investigators have studied the radiopacity of various medications.^{52,59,81,87,97,147,176,189,197} These investigators used an in vitro water-bath model to simulate the radiopacity of abdominal soft tissues.¹⁷⁶ The studies found that only a small number of medications exhibit some degree of radiopacity. A short list of the more consistently radiopaque xenobiotics is summarized in the mnemonic CHIPES—chloral hydrate, “heavy metals,” iron, phenothiazines, and enteric-

coated and sustained-release preparations.

The CHIPES mnemonic has several limitations.¹⁷⁶ It does not include all of the pills that are radiopaque in vitro such as acetazolamide and busulfan. Most radiopaque medications are only moderately radiopaque, and when ingested, they dissolve rapidly, becoming difficult or impossible to detect. “Psychotropic medications” include a wide variety of compounds of varying radiopacity.^{147,176} For example, whereas trifluoperazine (containing fluorine; atomic number 9) is radiopaque in vitro, chlorpromazine (containing chlorine; atomic number 17) is not.¹⁷⁶

Finally, sustained-release preparations and those with enteric coatings have variable composition and radiopacity. Pill formulations of fillers, binders, and coatings vary among manufacturers, and even a specific product can change depending on the date of manufacture. Furthermore, the insoluble matrix of some sustained-release preparations is radiopaque, and when seen on a radiograph, these tablets may no longer contain active medication. Some sustained-release cardiac medications such as verapamil and nifedipine have inconsistent radiopacity.^{119,188,199}

EXPOSURE TO A KNOWN XENOBIOTIC

When a xenobiotic that is known to be radiopaque is involved in an exposure, radiography plays an important role in patient care.⁵ Radiography can confirm the diagnosis of a radiopaque xenobiotic exposure, quantify the approximate amount of xenobiotic involved, and monitor its removal from the body. Examples include ferrous sulfate, sustained-release potassium chloride,¹⁹³ and heavy metals.

Iron Tablet Ingestion

Adult-strength ferrous sulfate tablets are readily detected radiographically because they are highly radiopaque and disintegrate slowly when ingested. Aside from confirming an iron tablet ingestion and quantifying the amount ingested, radiographs repeated after whole-bowel irrigation help to determine whether further GI decontamination is needed (Fig. 5–3).^{51,61,101,146,151,153,205} Nonetheless, caution must be exercised in using radiography to exclude an iron ingestion. Some iron preparations are not radiographically detectable. Liquid, chewable, or encapsulated (“Spansule”) iron preparations rapidly fragment and disperse after ingestion. Even when intact, these preparations are less radiopaque than ferrous sulfate tablets.⁵²

FIGURE 5-3. Iron tablet overdose. (A) Identification of the large amount of radiopaque tablets confirms the diagnosis in a patient with a suspected iron overdose and permits rough quantification of the amount ingested. (B) After emesis and whole-bowel irrigation, a second radiograph revealed some remaining tablets and indicated the need for further intestinal decontamination. (Used with permission of The Toxicology Fellowship of the New York City Poison Center.)

Metals

Metals, such as arsenic, cesium, lead, manganese, mercury, potassium, and thallium, can be detected radiographically. Examples of metal exposure include leaded ceramic glaze (Fig. 5-4),¹⁶⁸ paint chips containing lead (Fig. 96-6),^{112,133} mercuric oxide and elemental mercury (Fig. 98-1),¹²² thallium salts (atomic number 81),^{44,134} and zinc (atomic number 30).²³ Arsenic (Fig. 5-5)^{77,116,203} with a lower atomic number (atomic number 33) is also radiopaque.

FIGURE 5-4. An abdominal radiograph of a patient who intentionally ingested ceramic glaze containing 40% lead. (Used with permission of The Toxicology Fellowship of the New York City Poison Center.)

FIGURE 5-5. An abdominal radiograph in an elderly woman incidentally revealed radiopaque material in the pelvic region (arrowhead). This was residual from gluteal injection of antisypylis therapy she had received 35 to 40 years earlier. The injections may have contained an arsenical. (Used with permission of Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.)

Mercury. Unintentional ingestion of elemental mercury can occur when a glass thermometer or a long intestinal tube

with a mercury-containing balloon breaks. Liquid elemental mercury can be injected subcutaneously or intravenously. Radiographic studies assist débridement by detecting mercury that remains after the initial excision. Elemental mercury that is injected intravenously produces a dramatic radiographic picture of pulmonary embolization (Fig. 5–6).^{23,26,112,126,130,143}

FIGURE 5–6. Elemental mercury exposures. (A) Unintentional rupture of a Cantor intestinal tube distributed mercury throughout the bowel. (B) The chest radiograph in a patient after intravenous injection of elemental mercury showing metallic pulmonary embolism. The patient developed respiratory failure, pleural effusions, and uremia and died despite aggressive therapeutic interventions. (C) Subcutaneous injection of liquid elemental mercury is readily detected radiographically. Because mercury is systemically absorbed from subcutaneous tissues, it must be removed by surgical excision. (D) A radiograph after surgical débridement reveals nearly complete removal of the mercury deposit. Surgical staples and a radiopaque drain are visible. (Image A used with permission of Dr. Richard Lefleur, Department of Radiology, Bellevue Hospital Center; image B used with permission of Dr. N. John Stewart, Department of Emergency Medicine, Palmetto Health, University of South Carolina School of Medicine; and images C and D used with permission of The Toxicology Fellowship of the New York City Poison Center.)

Lead. Ingested lead can be detected only by abdominal radiography, such as in a child with lead poisoning who has ingested paint chips (Fig. 96–6). Metallic lead (eg, a bullet) that is embedded in soft tissues is not usually systemically absorbed. However, when the bullet is in contact with an acidic environment such as synovial fluid or cerebrospinal fluid

(CSF), there may be significant absorption. Over many years, mechanical and chemical action within the joint causes the bullet to fragment and gradually dissolve.^{43,45,53,192,196} Radiography can confirm the source of lead poisoning by revealing metallic material in the joint or CSF (Fig. 5–7).

FIGURE 5–7. A “lead arthrogram” discovered many years after a bullet wound to the shoulder. At the time of the initial injury, the bullet was embedded in the articular surface of the humeral head (arrow). The portion of the bullet that protruded into the joint space was surgically removed, leaving a portion of the bullet exposed to the synovial space. A second bullet was embedded in the muscles of the scapula. Eight years after the injury, the patient presented with weakness and anemia. Extensive lead deposition throughout the synovium is seen. The blood lead concentration was 91 $\mu\text{g/dL}$. (Used with permission of The Toxicology Fellowship of the New York City Poison Center.)

Xenobiotics in Containers

In some circumstances, ingested xenobiotics can be seen even though they are of similar radiopacity to surrounding soft tissues. If a xenobiotic is ingested in a container, the container itself may be visible.

Body Packers. “Body packers” are individuals who smuggle large quantities of illicit drugs across international borders in securely sealed packets.^{3,15,16,25,36,56,95,109,125,132,156,181,183,201} The uniformly shaped, oblong packets can be seen on abdominal radiographs either because there is a thin layer of air or metallic foil within the container wall or because the packets are outlined by bowel gas (Fig. 5–8). In some cases, a “rosette” representing the knot at the end of the packet is seen.¹⁸³ Intraabdominal calcifications (pancreatic calcifications and bladder stones) have occasionally been misinterpreted as drug-containing packets.^{201,217}

A

B

C

D

FIGURE 5–8. Three “body packers” showing the various appearances of drug packets. Drug smuggling is accomplished by packing the gastrointestinal tract with large numbers of manufactured, well-sealed containers. (A) Multiple oblong packages of uniform size and shape are seen throughout the bowel. (B) The packets are visible in this patient because they are surrounded by a thin layer of air within the wall of the packet. (C and D) Small bowel obstruction caused by drug packets in a man who developed abdominal pain and vomiting one day after arriving on a plane flight from Colombia. Computed tomography confirmed bowel obstruction, and the patient underwent laparotomy and removal of 15 packets through an enterotomy. (Images A and B used with permission of Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center. Images C and D used with permission of The Toxicology Fellowship of the New York City Poison

Control Center.)

The sensitivity of abdominal radiography for such packets is high, in the range of 85% to 90%. The major role of radiography is as a rapid screening test to confirm the diagnosis in individuals suspected of smuggling drugs, such as persons being held by airport customs agents. However, because packets are occasionally not visualized and the rupture of even a single packet can be fatal, abdominal radiography should not be relied on to exclude the diagnosis of body packing. Ultrasonography has also been used to rapidly detect packets, although it also should not be relied on to exclude such a life-threatening ingestion.^{33,78,136} After intestinal decontamination, an upper GI series with oral contrast or CT with or without enteric contrast can reveal any remaining packets.^{80,91,148}

Body Stuffers. A “body stuffer” is an individual who, in an attempt to avoid imminent arrest, hurriedly ingests contraband in insecure packaging.¹⁷⁰ The risk of leakage from such haphazardly constructed containers is high. Unfortunately, radiographic studies cannot reliably confirm or exclude such ingestions.¹⁸⁷

Occasionally, a radiograph will demonstrate the ingested container (Fig. 5–9). If the drug is in a glass or in a hard-plastic crack vial, the container may be seen.⁹⁰ If the body stuffer swallows soft plastic bags containing the drug, the containers are not usually visible. However, in three reported cases, “baggies” were visualized by abdominal CT.^{37,48,83,85,105,157,180}

FIGURE 5–9. Two “body stuffers.” Radiography infrequently helps with the diagnosis. (A) An ingested glass crack vial is seen in the distal bowel (arrow). The patient had ingested his contraband several hours earlier at the time of a police raid. Only the tubular-shaped container, and not the xenobiotic, is visible radiographically. The patient did not develop signs of cocaine intoxication during 24 hours of observation. (B) Another patient in police custody was brought to the emergency department for allegedly ingesting his drugs. The patient repeatedly denied this. The radiographs revealed “nonsurgical” staples in his abdomen (arrows). When questioned again, the patient admitted that he had swallowed several plastic bags that were stapled closed. (Used with permission of The Toxicology Fellowship of the New York City Poison Center.)

Halogenated Hydrocarbons

Some halogenated hydrocarbons can be visualized radiographically.^{31,38} Radiopacity is proportionate to the number of chlorine atoms. Both carbon tetrachloride (CCl_4) and chloroform (CHCl_3) are radiopaque. Because these liquids are immiscible in water, a triple layer may be seen within the stomach on an upright abdominal radiograph—an uppermost air bubble, a middle radiopaque chlorinated hydrocarbon layer, and a lower gastric fluid layer. However, these ingestions are rare, and the quantity ingested is usually too small to show this effect. Other halogenated hydrocarbons such as methylene iodide are highly radiopaque.²¹⁶

Mothballs

Some types of mothballs can be visualized by radiography. Whereas relatively nontoxic paradichlorobenzene mothballs (containing chlorine; atomic number 17) are moderately radiopaque, more toxic naphthalene mothballs are radiolucent.¹⁹⁴ If the patient is known to have swallowed mothballs, the difference in radiopacity may help determine the type. However, if mothball ingestion is not already suspected, the more toxic naphthalene type may not be detected. Radiographs of mothballs outside of the patient can help distinguish these two types (Fig. 105–2).

Radiolucent Xenobiotics

A radiolucent xenobiotic may be visible because it is less radiopaque than surrounding soft tissues. Hydrocarbons such as gasoline are relatively radiolucent when embedded in soft tissues. The radiographic appearance resembles subcutaneous gas as seen in a necrotizing soft tissue infection (Fig. 5–10).

FIGURE 5–10. Subcutaneous injection of gasoline into the antecubital fossa. The radiolucent hydrocarbon mimics gas in the soft tissues that is seen with a necrotizing soft tissue infection such as necrotizing fasciitis or gas gangrene (arrows). (Used with permission of The Toxicology Fellowship of the New York City Poison Center.)

EXTRAVASATION OF INTRAVENOUS CONTRAST MATERIAL

Extravasation of intravenous (IV) radiographic contrast material is a common occurrence. In most cases, the volume extravasated is small, and there are no clinical sequelae.^{17,35,54,169} Rarely, a patient has an extravasation large enough to cause cutaneous necrosis and ulceration.

Recently, the incidence of sizable extravasations has increased because of the use of rapid-bolus automated power injectors for CT studies.²⁰⁸ Fortunately, nonionic low-osmolality contrast solutions are currently nearly always used for these studies. These solutions are far less toxic to soft tissues than older ionic high-osmolality contrast materials.

The treatment of contrast extravasation has not been studied in a large series of human subjects and is therefore controversial. Various strategies have been proposed. The affected extremity should be elevated to promote drainage. Although topical application of heat causes vasodilation and could theoretically promote absorption of extravasated contrast material, the intermittent application of ice packs has been shown to lower the incidence of ulceration.³⁵ Rarely, an extremely large volume of liquid is injected into the soft tissues, which requires surgical decompression when there are signs of a compartment syndrome. A radiograph of the extremity will demonstrate the extent of extravasation (Fig. 5–11).³⁵

FIGURE 5–11. Extravasation of intravenous contrast into the soft tissues of the upper extremity that occurred during a computed tomography contrast bolus administered by a power injector. Despite the extensive extravasation, the patient was successfully managed with limb elevation and cool compresses. (Used with permission of Mark Bernstein, MD, Department of Radiology, New York University School of Medicine.)

Precautions should be taken to prevent extravasation. A recently placed, well-running IV catheter should be used. The distal portions of the extremities (hands, wrist, and feet) should not be used as IV sites for injecting contrast. Patients who are more vulnerable to complications and those whose veins may be more fragile, such as infants, debilitated patients, and those with an impaired ability to communicate, must be closely monitored to prevent or determine if extravasation occurs.

Summary

Obtaining an abdominal radiograph in an attempt to identify pills or other xenobiotics in a patient with an unknown ingestion is unlikely to be helpful and is, in general, not warranted. Radiography is most useful when the suspected xenobiotic is known to be radiopaque, as is the case with iron tablets and heavy metals. The xenobiotic can be radiographed within the patient’s abdomen; elsewhere in the patient’s body; or, if the material is available, outside of the patient.

VISUALIZING THE EFFECTS OF A XENOBIOTIC ON THE BODY

The lungs, central nervous system (CNS), GI tract, and skeleton are the organ systems that are most amenable to diagnostic imaging. Disorders of the lungs and skeletal system are seen by plain radiography. For abdominal pathology, contrast studies and CT are more useful, although plain radiographs can diagnose intestinal obstruction, perforation, and radiopaque foreign bodies. Imaging of the CNS uses CT, MRI, and nuclear scintigraphy (PET and SPECT).

Skeletal Changes Caused by Xenobiotics

A number of xenobiotics affect bone mineralization. Toxicologic effects on bone result in either increased or decreased density (Table 5–2). Some xenobiotics produce characteristic radiographic pictures, although exact diagnoses usually depend on correlation with the clinical scenario.^{10,145} Furthermore, alterations in skeletal structure develop gradually and are usually not visible unless the exposure continues for at least 2 weeks.

TABLE 5–2. Xenobiotic Causes of Skeletal Abnormalities

<i>Increased Bone Density</i>	<i>Diminished Bone Density (Either Diffuse Osteoporosis or Focal Lesions)</i>
<p>Metaphyseal bands (children): Lead, bismuth, phosphorus: Chondrosclerosis caused by toxic effect on bone growth</p> <p>Diffuse increased bone density: Fluorosis: Osteosclerosis (hyperostosis deformans), osteophytosis, ligament calcification; usually involves the axial skeleton (vertebrae and pelvis) and may cause compression of the spinal cord and nerve roots</p> <p>Bisphosphonates: Increased bone density (inhibition of osteoclast activity) Atypical insufficiency fractures proximal femoral shaft and subtrochanteric region</p> <p>Hypervitaminosis A (pediatric): Cortical hyperostosis and subperiosteal new bone formation; diaphyses of long bones have an undulating appearance</p> <p>Hypervitaminosis D: Generalized osteosclerosis, cortical thickening, and metaphyseal bands</p>	<p>Corticosteroids: Osteoporosis: Diffuse Osteonecrosis: Focal lesions, eg, avascular necrosis of the femoral head; loss of volume with both increased and decreased bone density; osteonecrosis also occurs in alcoholism, bismuth arthropathy, Caisson disease (dysbarism), trauma</p> <p>Hypervitaminosis D: Focal or generalized osteoporosis</p> <p>Injection drug use: Osteomyelitis (focal lytic lesions) caused by septic emboli; usually affects vertebral bodies and sternomanubrial joint</p> <p>Vinyl chloride monomer: Acroosteolysis (distal phalanges)</p>

Increase in Bone Density

Lead poisoning. Skeletal radiography may suggest the diagnosis of chronic lead poisoning even before the blood lead concentration is obtained. With lead poisoning, the metaphyseal regions of rapidly growing long bones develop transverse bands of increased density along the growth plate (Fig. 5-12).^{21,160,163,174} Characteristic locations are the distal femur and proximal tibia. Flaring of the distal metaphysis also occurs. Such lead lines are also seen in the vertebral bodies and iliac crest. Detected in approximately 80% of children with a mean lead concentration of $49 \pm 17 \mu\text{g/dL}$, lead lines usually occur in children between the ages of 2 and 9 years.²¹ In most children, it takes several weeks for lead lines to appear, although in very young infants (2–4 months old), lead lines may develop within days of exposure.²²¹ After exposure ceases, lead lines diminish and may eventually disappear.

FIGURE 5-12. (A) A radiograph of the knees of a child with lead poisoning. The metaphyseal regions of the distal femur and proximal tibia have developed transverse bands representing bone growth abnormalities caused by lead toxicity. The multiplicity of lines implies repeated exposures to lead. (B) The abdominal radiograph of the child shows many radiopaque flakes of ingested leaded paint chips. Lead poisoning also caused abnormally increased cortical mineralization of the vertebral bodies, which gives them a boxlike appearance. (Used with permission of Dr. Nancy Genieser, Department of Radiology, Bellevue Hospital Center.)

Lead lines are caused by the toxic effect of lead on bone growth and do not represent deposition of lead in bone. Lead impedes resorption of calcified cartilage in the zone of provisional calcification adjacent to the growth plate. This is termed chondrosclerosis.^{21,47} Other xenobiotics that cause metaphyseal bands are yellow phosphorus ([Chap. 116](#)), bismuth ([Chap. 90](#)), and vitamin D ([Chap. 47](#)).

Fluorosis. Fluoride poisoning causes a diffuse increase in bone mineralization. Endemic fluorosis occurs where drinking water contains very high levels of fluoride (≥ 2 or more parts per million), as an occupational exposure among aluminum workers handling cryolite (sodium–aluminum fluoride), or with excessive tea drinking. The skeletal changes associated with fluorosis are osteosclerosis (hyperostosis deformans), osteophytosis, and ligament calcification ([Fig. 5-13](#)). Fluorosis primarily affects the axial skeleton, especially the vertebral column and pelvis. Thickening of the vertebral

column may cause compression of the spinal cord and nerve roots. Without a history of fluoride exposure, the clinical and radiographic findings can be mistaken for osteoblastic skeletal metastases. The diagnosis of fluorosis is confirmed by histologic examination of the bone and measurement of fluoride levels in the bone and urine.^{22,210}

FIGURE 5-13. Skeletal fluorosis. A 28 year-old man developed progressive muscle and joint pain over 3 to 4 weeks particularly involving his hands with thickening of his fingers. An evaluation for inflammatory rheumatologic disorders was negative. Radiographs of his hands showed exuberant periosteal new bone formation known as “periostitis deformans,” which is characteristic of skeletal fluorosis. Further questioning revealed that the patient had been “huffing” the propellant of “Dust Off”; 225 cans were found at his residence. The propellant is difluoroethane (Freon 152a). The hydrocarbon is dehalogenated in the liver and chronic exposure results in fluoride toxicity. (Used with permission of Dr. Eric Lavonas, Rocky Mountain Poison and Drug Center, Denver Health and Hospital Authority, Denver, CO, and Dr. Shawn M. Varney, Department of Emergency Medicine, San Antonio Military Medical Center, TX.)

Bisphosphonates. Bisphosphonates such as alendronate (Fosamax) are commonly used to treat osteoporosis. They increase bone density by inhibiting osteoclast activity and decreasing bone resorption. However, by suppressing bone turnover and fracture healing, bisphosphonates are associated with accumulated microdamage to bone and skeletal weakening, which makes the bone vulnerable to fractures. Radiographically, there is thickening of the cortex of diaphyseal bone, typically the proximal femoral shaft. Such bone is associated with atypical proximal femoral shaft and subtrochanteric fractures after low-energy injuries such as a fall from standing. The fractures are transverse and have a characteristic “beaked” appearance caused by the cortical thickening (Fig. 5-14).

FIGURE 5–14. Biphosphonate (alendronate) associated proximal femoral shaft fracture. A 61 year-old woman tripped on the sidewalk, falling on to her right side. She had been taking alendronate (Fosamax) for 3 years for osteoporosis. There is diffuse cortical thickening of the femoral shaft and a transverse fracture in the subtrochanteric region with “beaking” of the fractured cortex on the medial side of the fracture.

Focal Loss of Bone Density. Skeletal disorders associated with focal diminished bone density (or mixed rarefaction and sclerosis) include osteonecrosis, osteomyelitis, and osteolysis. Osteonecrosis, also known as avascular necrosis, most often affects the femoral head, humeral head, and proximal tibia.¹²⁷ There are many causes of osteonecrosis. Xenobiotic causes include long-term corticosteroid use and alcoholism. Radiographically, focal skeletal lucencies and sclerosis are seen, ultimately with loss of bone volume and collapse (**Fig. 5–15A**).

FIGURE 5-15. (A) Avascular necrosis causing collapse of the femoral head in a patient with long-standing steroid-dependent asthma (arrow). (B and C) Vertebral osteomyelitis in an injection drug user who presented with posterior thoracic pain for 2 weeks and then lower extremity weakness. As seen on CT, the infection begins in the intervertebral disk and then spreads to the adjacent vertebral bodies. Magnetic resonance image shows extension into the spinal canal causing spinal cord compression. (D) An injection drug user with thoracic back pain, leg weakness, and low-grade fever. Radiographic and CT findings of the spine were negative. Magnetic resonance image showing an epidural abscess (arrow) compressing the spinal cord. The cerebrospinal fluid in the compressed thecal sac is bright on this T2-weighted image. (From Levitan R: Thoracolumbar spine. In Schwartz, Reisdorff EJ, eds: Emergency Radiology. New York, McGraw-Hill; 2000:343, with permission.)

Acroosteolysis. Acroosteolysis is bone resorption of the distal phalanges and is associated with occupational exposure

to vinyl chloride monomer. Protective measures have reduced its incidence since it was first described in the early 1960s.¹⁶⁴

Osteomyelitis. Osteomyelitis is a serious complication of injection drug use. It usually affects the axial skeleton, especially the vertebral bodies, as well as the sternomanubrial and sternoclavicular joints (Figs. 5–15B and C).^{74,79} Back pain or neck pain in injection drug users warrants careful consideration. A spinal epidural abscess causing spinal cord compression may accompany vertebral osteomyelitis.^{92,125} Radiographic findings are negative early in the disease course before skeletal changes are visible and the diagnosis is confirmed by MRI or CT (Fig. 5–15D).

Soft Tissue Changes

Certain abnormalities in soft tissues, predominantly as a consequence of infectious complications of injection drug use, are amenable to radiographic diagnosis.^{74,75,79,99,198} In an injection drug user who presents with signs of local soft tissue infections, radiography is indicated to detect a retained metallic foreign body, such as a needle fragment, or subcutaneous gas, as may be seen in a necrotizing soft tissue infection such as necrotizing fasciitis. CT is more sensitive at detecting soft tissue gas than is conventional radiography. CT and ultrasonography can also detect subcutaneous or deeper abscesses that require surgical or percutaneous drainage.

Pulmonary and Other Thoracic Problems

Many xenobiotics that affect intrathoracic organs produce pathologic changes that can be detected on chest radiographs.^{9,12,24,49,63,75,140,172,219} The lungs are most often affected, resulting in dyspnea or cough, but the pleura, hilum, heart, and great vessels may also be involved.⁶ Patients with chest pain may have a pneumothorax, pneumomediastinum, or aortic dissection. Patients with fever, with or without respiratory symptoms, may have a focal infiltrate, pleural effusion, or hilar lymphadenopathy.

Chest radiographic findings may suggest certain diseases, although the diagnosis ultimately depends on a thorough clinical history. When a specific xenobiotic exposure is known or suspected, the chest radiograph can confirm the diagnosis and help in assessment. If a history of xenobiotic exposure is not obtained, a patient with an abnormal chest radiograph may initially be misdiagnosed as having pneumonia or another disorder that is more common than xenobiotic-mediated lung disease.¹⁶⁶ Therefore, patients with chest radiographic abnormalities should be carefully questioned regarding possible xenobiotic exposures at work or at home, as well as the use of medications or other drugs.

Many pulmonary disorders are radiographically detectable because they result in fluid accumulation within the normally air-filled lung. Fluid may accumulate within the alveolar spaces or interstitial tissues of the lung, producing the two major radiographic patterns of pulmonary disease: airspace filling and interstitial lung disease (Table 5–3). Most xenobiotics are widely distributed throughout the lungs and produce a diffuse rather than a focal radiographic abnormality.

TABLE 5–3. Chest Radiographic Findings in Toxicologic Emergencies

<i>Radiographic Finding</i>	<i>Responsible Xenobiotic</i>	<i>Disease Processes</i>
Diffuse airspace filling	Salicylates Opioids Paraquat Irritant gases: NO ₂ (silo filler's disease), phosgene (COCl ₂), Cl ₂ , H ₂ S Organic phosphorus compounds, carbamates Alcoholic cardiomyopathy, cocaine, doxorubicin, cobalt	Acute respiratory distress syndrome Cholinergic stimulation (bronchorrhea) Congestive heart failure
Focal airspace filling	Low-viscosity hydrocarbons Gastric contents aspiration: CNS depressants, alcohol, seizures	Aspiration pneumonia
Multifocal airspace filling	Injection drug user	Septic emboli
Interstitial patterns: Fine or coarse reticular or reticulonodular pattern Patchy airspace filling is seen in some cases	Inhaled organic allergens: Farmer's lung, pigeon breeder's lung Nitrofurantoin, penicillamine Antineoplastics: Busulfan, bleomycin, carmustine, cyclophosphamide, methotrexate Amiodarone Talcosis (illicit drug contaminant) Pneumoconiosis: Asbestosis, silicosis, coal dust, berylliosis (chronic)	Hypersensitivity pneumonitis Cytotoxic lung damage Phospholipidosis Injected particulates Inhaled inorganic particulates
Pleural effusion	Procainamide, hydralazine, INH, methyldopa	Drug-induced SLE
Pneumomediastinum Pneumothorax	"Crack" cocaine and marijuana (forceful inhalation), syrup of ipecac and alcoholism (forceful vomiting), subclavian vein injection puncture	Barotrauma
Pleural plaques (calcified)	Asbestos exposure	Fibrosis or asbestosis
Lymphadenopathy	Phenytoin, methotrexate (rare) Silicosis (eggshell calcification), berylliosis	Pseudolymphoma Pneumoconiosis
Cardiomegaly (chronic exposure)	Ethanol, doxorubicin, cocaine, cobalt amphetamine, ipecac syrup Drug-induced systemic lupus erythematosus (procainamide, hydralazine, INH)	Dilated cardiomyopathy Pericardial effusion
Aortic enlargement	Cocaine	Aortic dissection

CNS = central nervous system; INH = isoniazid; SLE = systemic lupus erythematosus.

Diffuse Airspace Filling. Overdose with various xenobiotics, including salicylates, opioids, and paraquat, may cause acute respiratory distress syndrome (ARDS) (formerly known as noncardiogenic pulmonary edema or acute lung injury) with or without diffuse alveolar damage and characterized by leaky capillaries (Fig. 5–16).^{75,85,89,123,184,191,218} There are, of course, many other causes of ARDS, including sepsis, anaphylaxis, and major trauma.²¹³ Other xenobiotic exposures that may result in diffuse airspace filling include inhalation of irritant gases that are of low water solubility such as phosgene (COCl₂), nitrogen dioxide (silo filler's disease), chlorine, hydrogen sulfide, and sulfur dioxide (Chaps. 124 and 126).^{79,102} Organic phosphorus insecticide poisoning causes cholinergic hyperstimulation, resulting in bronchorrhea (Chap. 113). Smoking "crack" cocaine is associated with diffuse alveolar hemorrhage (Chap. 78).^{60,75,79,165,219}

FIGURE 5–16. Diffuse airspace filling. The chest radiograph of a patient who had recently injected heroin intravenously presented with respiratory distress and acute respiratory distress syndrome. The heart size is normal.

Focal Airspace Filling. Focal infiltrates are usually caused by bacterial pneumonia, although aspiration of gastric contents also causes localized airspace disease.^{75,195} Aspiration may occur during sedative–hypnotic or alcohol intoxication or during a seizure. During ingestion, low-viscosity hydrocarbons often enter the lungs while they are being swallowed (Figs. 5–17 and 108–1). There may be a delay in the development of radiographic abnormalities, and the chest radiograph may not appear to be abnormal until 6 hours after the ingestion.⁸ During aspiration, the most dependent portions of the lung are affected. When the patient is upright at the time of aspiration, the lower lung segments are involved. When the patient is supine, the posterior segments of the upper and lower lobes are affected.⁶²

FIGURE 5–17. Focal airspace filling as a result of hydrocarbon aspiration. A 34 year-old man aspirated gasoline. The chest radiograph shows bilateral lower lobe infiltrates.

Multifocal Airspace Filling. Multifocal airspace filling occurs with septic pulmonary emboli, which is a complication of injection drug use and right-sided bacterial endocarditis. The foci of pulmonary infection often undergo necrosis and cavitation (Fig. 5–18).^{75,79}

FIGURE 5–18. Multifocal airspace filling. The chest radiograph in an injection drug user who presented with high fever but without pulmonary symptoms. Multiple ill-defined pulmonary opacities are seen throughout both lungs, which are characteristic of septic pulmonary emboli. His blood cultures grew *Staphylococcus aureus*.

Interstitial Lung Diseases. Toxicologic causes of interstitial lung disease include hypersensitivity pneumonitis, use of medications with direct pulmonary toxicity, and inhalation or injection of inorganic particulates.⁷⁵ Interstitial lung diseases may have an acute, subacute, or chronic course. On the chest radiograph, acute and subacute disorders cause a fine reticular or reticulonodular pattern (Fig. 5–19). Chronic interstitial disorders cause a coarse reticular “honeycomb” pattern.

FIGURE 5–19. Reticular interstitial pattern. The chest radiograph of a patient with cardiac disease who presented to the

ED with progressive dyspnea. The initial diagnostic impression was interstitial pulmonary edema. The patient was taking amiodarone for malignant ventricular dysrhythmias (note the implanted automatic defibrillator). The lack of response to diuretics and the high-resolution CT pattern suggested that this was toxicity to amiodarone. The medication was stopped, and there was partial clearing over several weeks. (Used with permission of Dr. Georgeann McGuinness, Department of Radiology, New York University.)

Hypersensitivity Pneumonitis. Hypersensitivity pneumonitis is a delayed-type hypersensitivity reaction to an inhaled or ingested allergen.^{40,96,166} Inhaled organic allergens such as those in moldy hay (farmer's lung) and bird droppings (pigeon breeder's lung) cause hypersensitivity pneumonitis in sensitized individuals. There are two clinical syndromes: an acute, recurrent illness and a chronic, progressive disease. The acute illness presents with fever and dyspnea. In these cases, the chest radiograph findings are normal or may show fine interstitial or alveolar infiltrates. Chronic hypersensitivity pneumonitis causes progressive dyspnea, and the radiograph shows interstitial fibrosis.

The most common medication causing hypersensitivity pneumonitis is nitrofurantoin. Respiratory symptoms occur after taking the medication for 1 to 2 weeks. Other medications that may cause hypersensitivity pneumonitis include sulfonamides and penicillins.

Chemotherapeutics. Various chemotherapeutic agents, such as busulfan, bleomycin, cyclophosphamide, and methotrexate, cause pulmonary injury by their direct cytotoxic effect on alveolar cells.^{39,65} The radiographic pattern is usually interstitial (reticular or nodular) but may include airspace filling or mixed patterns. The patient presents with dyspnea, fever, and pulmonary infiltrates that begin after several weeks of therapy. Other causes of these clinical and radiographic findings must be considered, including opportunistic infection, pulmonary carcinomatosis, pulmonary edema, and intraparenchymal hemorrhage. Symptoms usually resolve with discontinuation of the offending medication.

Amiodarone. Amiodarone toxicity causes phospholipid accumulation within alveolar cells and may result in pulmonary fibrosis. An interstitial radiographic pattern is seen, although airspace filling may also occur (Fig. 5–19) (Chap. 64).

Particulates. Inhaled inorganic particulates, such as asbestos, silica, and coal dust, cause pneumoconiosis. This is a chronic interstitial lung disease characterized by interstitial fibrosis and loss of lung volume.^{32,138,167,215} IV injection of illicit xenobiotics that have particulate contaminants, such as talc, causes a chronic interstitial lung disease known as talcosis.^{1,55,212}

Pleural Disorders. Asbestos-related calcified pleural plaques develop many years after asbestos exposure (Fig. 5–20). These lesions do not cause clinical symptoms and have only a minor association with malignancy and interstitial lung disease. Asbestos-related pleural plaques should not be called asbestosis because that term refers specifically to the interstitial lung disease caused by asbestos. Pleural plaques must be distinguished from mesotheliomas, which are not calcified, enlarge at a rapid rate, and erode into nearby structures such as the ribs.

A

B

FIGURE 5–20. (A) Calcified plaques typical of asbestos exposure are seen on the pleural surfaces of the lungs, diaphragm, and heart. The patient was asymptomatic; this was an incidental radiographic finding. (B) The CT scan demonstrates that the opacities seen on the chest radiograph do not involve the lung itself. A lower thoracic image shows calcified pleural plaques (the diaphragmatic plaque is seen on the right). The CT confirms that there is no interstitial lung disease (“asbestosis”).

Pleural effusions occur with drug-induced systemic lupus erythematosus (SLE).¹⁴⁰ The medications most frequently implicated are procainamide, hydralazine, isoniazid, and methyldopa. The patient presents with fever as well as other symptoms of SLE.

Pneumothorax and pneumomediastinum are associated with illicit drug use. These complications are related to the route of administration rather than to the particular drug. Barotrauma associated with the Valsalva maneuver or intense inhalation with breath holding during the smoking of “crack” cocaine or marijuana results in pneumomediastinum (Fig. 5–21A).^{20,50,75,150} Pneumomediastinum is one cause of cocaine-related chest pain that can be diagnosed by chest radiography. Forceful vomiting after ingestion of syrup of ipecac or alcohol may produce a Mallory-Weiss syndrome, pneumomediastinum, and mediastinitis (Boerhaave syndrome).²²⁰ IV drug users who attempt to inject into the subclavian and internal jugular veins may cause a pneumothorax.⁴⁶

FIGURE 5-21. Two patients with chest pain after cocaine use. (A) Pneumomediastinum after forceful inhalation while smoking “crack” cocaine. A fine white line representing the pleura elevated from the mediastinal structures is seen (arrows). The patient’s chest pain resolved during a 24-hour period of observation. (B to D) Thoracic aortic dissection after cocaine use. The patient presented with chest pain radiating to the back. He had a history of hypertension and was noncompliant with medications. Chest radiography shows an enlarged aorta caused by aortic wall weakening secondary to his long-standing hypertension. Computed tomography angiography shows the intraluminal dissection flap originating at the left subclavian artery and extending into the descending aorta. (Image A used with permission of The Toxicology Fellowship of the New York City Poison Control Center.)

Lymphadenopathy. Phenytoin may cause drug-induced lymphoid hyperplasia with hilar lymphadenopathy.¹⁴⁰ Chronic beryllium exposure results in hilar lymphadenopathy that mimics sarcoidosis, with granulomatous changes in the lung parenchyma. Silicosis is associated with “eggshell” calcification of hilar lymph nodes.

Cardiovascular Abnormalities. Dilated cardiomyopathy occurs in chronic alcoholism and exposure to cardiotoxic medications such as doxorubicin (Adriamycin). Enlargement of the cardiac silhouette may also be caused by a pericardial effusion, which may accompany drug-induced SLE. Aortic dissection is associated with use of cocaine and amphetamines.^{66,75,114,152,162} The chest radiograph may show an enlarged or indistinct aortic knob and an ascending or descending aorta (Figs. 5-21B to D).

Abdominal Problems

Abdominal imaging modalities include conventional radiography, CT, GI contrast studies, and angiography.⁶⁸ Conventional radiography is limited in its ability to detect most intraabdominal pathology because most pathologic processes involve soft tissue structures that are not well seen. Plain radiography readily visualizes gas in the abdomen and is therefore usable to

diagnose pneumoperitoneum (free intraperitoneal air) and bowel distension caused by mechanical obstruction or diminished gut motility (adynamic ileus). Other abnormal gas collections, such as intramural gas associated with intestinal infarction, are seen infrequently (Table 5–4).^{73,120,128,137,186}

TABLE 5–4. Plain Abdominal Radiography in Toxicologic Emergencies

<i>Radiographic Finding</i>	<i>Xenobiotic</i>
Pneumoperitoneum (hollow viscus perforation)	Caustics: Iron, alkali, acids Cocaine GI decontamination (syrup of ipecac, lavage tube)
Mechanical obstruction intraluminal foreign body Intestinal gastric outlet } Upper GI esophageal } series	Foreign-body ingestion: Body packer, enteric-coated pills (bezoar)
Ileus (diminished gut motility)	Opioids Anticholinergics Cyclic antidepressants Mesenteric ischemia (cocaine, oral contraceptives, cardioactive steroids, hypokalemia, hypomagnesemia)
Intramural gas (intestinal infarction) Bowel wall thickening Hepatic portal venous gas (CT is more sensitive)	Cocaine Ergot alkaloids Oral contraceptives Calcium channel blockers Hypotension
Foreign-body ingestion	Iron pills Metals (As, Cs, Hg, Pb, Tl) Body packers and stuffers Bismuth subsalicylate Calcium carbonate Enteric-coated and sustained-release tablets Pica (calcareous clay)

Pneumoperitoneum. GI perforation is diagnosed by seeing free intraperitoneal air under the diaphragm on an upright chest radiograph. Peptic ulcer perforation is associated with crack cocaine use.^{2,29,107} Esophageal or gastric perforation (or tear) can be a complication of forceful emesis induced by syrup of ipecac or alcohol intoxication or attempted placement of a large-bore orogastric tube (Fig. 5–22).²²⁰ Esophageal and gastric perforation may also occur after the ingestion of caustics such as iron, alkali, or acid.¹⁰³ Esophageal perforation causes pneumomediastinum and mediastinitis.

FIGURE 5–22. Gastrointestinal perforation after gastric lavage with a large-bore orogastric tube. The upright chest radiograph shows air under the right hemidiaphragm and pneumomediastinum (arrows). An esophagram with water-soluble contrast did not demonstrate the perforation. Laparotomy revealed perforation of the anterior wall of the stomach.

Obstruction and Ileus. Both mechanical bowel obstruction and adynamic ileus (diminished gut motility) cause bowel distension. With mechanical obstruction, there is a greater amount of intestinal distension proximal to the obstruction and a relative paucity of gas and intestinal collapse distal to the obstruction. In adynamic ileus, the bowel distension is relatively uniform throughout the entire intestinal tract. On the upright abdominal radiograph, both mechanical obstruction and adynamic ileus show air-fluid levels. In mechanical obstruction, air-fluid levels are seen at different heights and produce a “stepladder” appearance.

Mechanical bowel obstruction may be caused by large intraluminal foreign bodies such as a body packer’s packets or a medication bezoar.^{64,197} Adynamic ileus may result from the use of opioids, anticholinergics, and tricyclic antidepressants (Fig. 5–23).^{15,68} Because adynamic ileus occurs in many diseases, the radiographic finding of an ileus is not helpful diagnostically. When the distinction between obstruction and adynamic ileus cannot be made based on the abdominal radiographs, abdominal CT can clarify the diagnosis.¹³⁵

FIGURE 5–23. Methadone maintenance therapy causing marked abdominal distension. The radiograph reveals striking

large bowel dilatation, termed colonic ileus, caused by chronic opioid use. A similar radiographic picture is seen with anticholinergic poisoning. A contrast enema can clarify the diagnosis. (Used with permission of Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.)

Mesenteric Ischemia. In most patients with intestinal ischemia, plain abdominal radiographs show only a nonspecific or adynamic ileus pattern. In a small proportion of patients with ischemic bowel (5%), intramural gas is seen.¹⁵ Rarely, gas is also seen in the hepatic portal venous system. CT is better able to detect signs of mesenteric ischemia, particularly bowel wall thickening (Fig. 5–24).¹⁴

FIGURE 5–24. Bowel infarction in a 50 year-old man with an aspirin overdose. He presented with renal failure, hypotension, and altered mental status. The next day after hemodialysis and hemofiltration, he developed abdominal distension and fever. Abdominal computed tomography showed extensive intramural gas (arrow) caused by bowel infarction, and the patient underwent surgical bowel resection.

Intestinal ischemia and infarction may be caused by use of cocaine; other sympathomimetics; and the ergot alkaloids, all of which induce mesenteric vasoconstriction.^{79,110,130} Calcium channel blocker overdoses cause splanchnic vasodilation and hypotension that may result in intestinal ischemia. Superior mesenteric vein thrombosis may be caused by hypercoagulability associated with chronic oral contraceptive use.

Gastrointestinal Hemorrhage and Hepatotoxicity. Radiography is not usually helpful in the diagnosis of such common abdominal complications as GI bleeding and hepatotoxicity.

The now obsolete radiocontrast agent thorium dioxide (Thorotrast; thorium, atomic number 90) provides a unique example of pharmaceutical-induced hepatotoxicity. It was used as an angiographic contrast agent until 1947, when it was found to cause hepatic malignancies. The radioactive isotope of thorium has a half-life of 400 years. It accumulates within the reticuloendothelial system and remains there for the life of the patient. It had a characteristic radiographic appearance, with multiple punctate opacities in the liver, spleen, and lymph nodes (Fig. 5–25). Patients who received thorium before its removal from the market may still present with hepatic malignancies.^{18,204}

FIGURE 5–25. An abdominal radiograph of a patient who had received thorium dioxide (Thorotrast) for a radiocontrast study many years previously. The spleen (vertical white arrowhead), liver (horizontal black arrowhead), and lymph nodes (horizontal white arrowhead) are demarcated by thorium retained in the reticuloendothelial system. (Used with permission of Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.)

Contrast Esophagram and Upper Gastrointestinal Series. Ingestion of a caustic may cause severe damage to the mucosal lining of the esophagus. This can be demonstrated by a contrast esophagram. However, in the acute setting, upper endoscopy should be performed rather than an esophagram because it provides more information about the extent of injury and prognosis.¹¹¹ In addition, administration of barium will coat the mucosa, making endoscopy difficult. For later evaluation, a contrast esophagram identifies mucosal defects, scarring, and stricture formation (Figs. 5–26 and 106–4).¹²⁹

FIGURE 5–26. (A) A barium swallow performed several days after ingestion of liquid lye shows intramural dissection and extravasation of barium with early stricture formation. (B) At 3 weeks after ingestion, there is an absence of peristalsis, diffuse narrowing of the esophagus, and reduction in size of the fundus and antrum of the stomach as a result of scarring. (Used with permission of Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.)

The choice of radiographic contrast agent (barium or water-soluble material) depends on the clinical situation. If the esophagus is severely strictured and there is a risk of aspiration, barium should be used because water-soluble contrast material is damaging to the pulmonary parenchyma. If, on the other hand, esophageal or gastric perforation is suspected,

water-soluble contrast is safer because extravasated barium is highly irritating to mediastinal and peritoneal tissues, but extravasated water-soluble contrast is gradually absorbed into the circulation.

Ingested foreign bodies may cause esophageal and gastric outlet obstruction. Esophageal obstruction caused by a drug packet can be demonstrated by a contrast esophagram. Concretions of ingested material in the stomach may cause gastric outlet obstruction. This has been reported with potassium chloride tablets and enteric-coated aspirin.^{11,185}

Abdominal Computed Tomography. CT provides great anatomic definition of intraabdominal organs and plays an important role in the diagnosis of a wide variety of abdominal disorders. In most cases, both oral and IV contrast are administered. Oral contrast delineates the intestinal lumen. IV contrast is needed to reliably detect lesions in hepatic and splenic parenchyma, the kidneys, and the bowel wall.

Certain abdominal complications of poisonings are amenable to CT diagnosis. Intestinal ischemia causes bowel wall thickening; intramural hemorrhage; and at a later stage, intramural gas and hepatic portal venous gas (Fig. 5-24).¹⁴ Hepatic portal venous gas can also be seen after ingestion of 3% hydrogen peroxide. Splenic infarction and splenic and psoas abscesses are complications of IV drug use that may be diagnosed on CT.¹⁵ Radiopaque foreign substances such as intravenously injected elemental mercury may be detected and accurately localized by CT.¹²⁶ Radiolucent foreign bodies, such as a body packer's packets, may be detected by using enteric contrast.^{83,85}

Vascular Lesions. Angiography may detect such complications of injection drug use as venous thrombosis and arterial laceration causing pseudoaneurysm formation (Figs. 5-27 and 5-28). IV injection of amphetamine, cocaine, or ergotamine causes necrotizing angiitis that is associated with microaneurysms, segmental stenosis, and arterial thrombosis. These lesions are seen in the kidneys, small bowel, liver, pancreas, and cerebral circulation (Fig. 5-29).^{34,161} Complications include aneurysm rupture and visceral infarction. Renal lesions cause severe hypertension and acute kidney injury.¹⁷⁵

FIGURE 5-27. (A) Chest radiograph of a young drug abuser who used the supraclavicular approach for heroin injection. The large mass in the left chest was suspicious for a pseudoaneurysm. (B) An arch aortogram performed on the patient revealed a large pseudoaneurysm and hematoma subsequent to an arterial tear during attempted injection. Surgical repair was performed. (Used with permission of Dr. Richard Lefleur, Department of Radiology, Bellevue Hospital.)

FIGURE 5–28. Venogram of a 50 year-old patient who routinely injected heroin into his groin. Occlusion of the femoral vein (black arrowhead) with diffuse aneurysmal dilatation (small arrowhead) and extensive collaterals are shown. Incidental radiopaque materials are noted in the right buttock (double arrowheads). By history, this represents either bismuth or arsenicals he received as antisypilitic therapy. (Used with permission of Dr. Richard Lefleur, Department of Radiology, Bellevue Hospital.)

FIGURE 5–29. A selective renal angiogram in an injection methamphetamine user demonstrating multiple small and large aneurysms (arrowheads). (Used with permission of Dr. Richard Lefleur, Department of Radiology, Bellevue Hospital Center.)

Neurologic Problems

Diagnostic imaging studies have revolutionized the management of CNS disorders.^{57,71} Both acute brain lesions and chronic degenerative changes can be detected (Table 5–5).¹¹⁸ Some xenobiotics have a direct toxic effect on the CNS; others indirectly cause neurologic injury by causing hypoxia, hypotension, hypertension, cerebral vasoconstriction, head trauma,

or infection.

TABLE 5–5. Head Computed Tomography (Noncontrast) in Toxicologic Emergencies

<i>CT Finding</i>	<i>Brain Lesion</i>	<i>Xenobiotic Etiology</i>
Hemorrhage	Intraparenchymal hemorrhage	Sympathomimetics: cocaine (“crack”), amphetamine, phenylpropanolamine, phencyclidine, ephedrine, pseudoephedrine
	Subarachnoid hemorrhage	Mycotic aneurysm rupture (IDU)
	Subdural hematoma	Trauma secondary to ethanol, sedative-hypnotics, seizures Anticoagulants
Brain lucencies	Basal ganglia focal necrosis (also subcortical white matter lucencies)	Carbon monoxide, cyanide, hydrogen sulfide, methanol, manganese
	Stroke: Vasoconstriction	Sympathomimetics: cocaine (“crack”), amphetamine, phenylpropanolamine, phencyclidine, ephedrine, pseudoephedrine, ergotamine
	Mass lesion: tumor, abscess	Septic emboli, AIDS-related CNS toxoplasmosis or lymphoma
Loss of brain tissue	Atrophy: Cerebral, cerebellar	Alcoholism, toluene

CNS = central nervous system; CT = computed tomography; IDU = injection drug use.

Imaging Modalities. CT can directly visualize brain tissue and many intracranial lesions.⁷⁰ CT is the imaging study of choice in the emergency setting because it readily detects acute intracranial hemorrhage as well as parenchymal lesions that are causing mass effect. CT is fast, is widely available on an emergency basis, and can accommodate critical support and monitoring devices. Infusion of IV contrast further delineates intracerebral mass lesions such as tumors and abscesses.

MRI has largely supplanted CT in nonemergency neurodiagnosis. It offers better anatomic discrimination of brain tissues and areas of cerebral edema and demyelination. However, MRI is no better than CT in detecting acute blood collections or mass lesions. In the emergency setting, the disadvantages of MRI outweigh its strengths. MRI is usually not readily available on an emergency basis, image acquisition time is long, and critical care supportive and monitoring devices are often incompatible with MR scanning machines.¹²¹

Nuclear scintigraphy that uses CT technology (SPECT and PET) is being used as a tool to elucidate functional characteristics of the CNS. Examples include both immediate and long-term effects of various xenobiotics on regional brain metabolism, blood flow, and neurotransmitter function.^{115,154,207}

Emergency Head Computed Tomography Scanning. An emergency noncontrast head CT scan is obtained to detect acute intracranial hemorrhage and focal brain lesions causing cerebral edema and mass effect. Patients with these lesions present with focal neurologic deficits, seizures, headache, or altered mental status. Toxicologic causes of intraparenchymal and subarachnoid hemorrhage include cocaine and other sympathomimetics (Fig. 5–30).^{113,117} Cocaine-induced vasospasm may cause ischemic infarction, although this is not well seen by CT until 6 to 24 or more hours after onset of the neurologic deficit (Fig. 5–31). Drug-induced CNS depression, most commonly ethanol intoxication, predisposes the patient to head trauma, which may result in a subdural hematoma or cerebral contusion (Fig. 5–32). Toxicologic causes of intracerebral mass lesions include septic emboli complicating injection drug use and HIV-associated CNS toxoplasmosis and lymphoma (Fig. 5–33).^{19,74,79,149} On a contrast CT, such tumors and focal infections exhibit a pattern of “ring enhancement.”

FIGURE 5–30. Subarachnoid hemorrhage after intravenous cocaine use. The patient had sudden severe headache followed by a generalized seizure. Extensive hemorrhage is seen surrounding the midbrain (white arrows) and in the right Sylvian fissure (black arrow). Angiography revealed an aneurysm at the origin of the right middle cerebral artery.

FIGURE 5–31. Acute stroke confirmed by diffusion-weighted magnetic resonance image (MRI). A 39 year-old man presented with left facial weakness that began 3 hours earlier after smoking crack cocaine. He also complained of left arm “tingling” but had normal examination findings. An emergency noncontrast computed tomography (CT) scan was obtained that was interpreted as normal (A), although in retrospect there was subtle loss of the normal gray–white differentiation (arrow). MRI was obtained to confirm that the facial palsy was a stroke and not a peripheral seventh cranial nerve palsy. Standard MRI sequence (T1-weighted, T2-weighted, and FLAIR) were normal in this early ischemic lesion (B and C). Diffusion-weighted imaging is able to show such early ischemic change—cytotoxic (intracellular) edema (D). The patient’s facial paresis improved but did not entirely resolve. A repeat CT scan 2 days later showed an evolving (subacute) infarction with vasogenic edema (E). Infarction was presumably caused by vasospasm because no carotid artery lesion or cardiac source of embolism was found. (From Schwartz DT: Emergency Radiology: Case Studies, New York, McGraw-Hill; 2008:517, with permission.)

FIGURE 5–32. An acute subdural hematoma in a patient with alcoholism after an alcohol binge. A crescent-shaped blood collection is seen between the right cerebral convexity and the inner table of the skull (arrow).

FIGURE 5–33. An injection drug user with ring-enhancing intracerebral lesions. The patient presented with fever and

altered mental status. In this patient, the lesions represent multiple septic emboli complicating acute *Staphylococcus aureus* bacterial endocarditis. A similar ring-enhancing appearance is seen with lesions caused by toxoplasmosis or primary central nervous system lymphoma in patients with AIDS. This patient was HIV negative.

Xenobiotic-Mediated Neurodegenerative Disorders. A number of xenobiotics directly damage brain tissue, producing morphologic changes that may be detectable using CT and MRI. Such changes include generalized atrophy, focal areas of neuronal loss, demyelination, and cerebral edema. Imaging abnormalities may help establish a diagnosis or predict prognosis in a patient with neurologic dysfunction after a xenobiotic exposure. In some cases, the imaging abnormality will suggest a toxicologic diagnosis in a patient with a neurologic disorder in whom a xenobiotic exposure was not suspected clinically.^{4,13,57,100,104,155,165,214}

Atrophy. Ethanol is the most widely used neurotoxin. With long-term ethanol use, there is a widespread loss of neurons and resultant atrophy. In some individuals with alcoholism, the loss of brain tissue is especially prominent in the cerebellum. However, the amount of cerebral or cerebellar atrophy does not always correlate with the extent of cognitive impairment or gait disturbance.^{42,67,84,86,106,209,211} Chronic solvent exposure, such as to toluene (occupational and illicit use), also causes diffuse cerebral atrophy.^{93,171}

Focal Degenerative Lesions. Carbon monoxide poisoning produces focal degenerative lesions in the brain. In about half of patients with severe neurologic dysfunction after carbon monoxide poisoning, CT scans show bilateral symmetrical lucencies in the basal ganglia, particularly the globus pallidus (**Figs. 5–34 and 125–1**).^{27,94,100,141,155,158,159,177,178,182,200,206} The basal ganglia are especially sensitive to hypoxic damage because of their limited blood supply and high metabolic requirements. Subcortical white matter lesions also occur after carbon monoxide poisoning. Although less frequent than lesions of the basal ganglia, white matter lesions are more clearly associated with a poor neurologic outcome. MRI is more sensitive than CT at detecting these white matter abnormalities.^{27,57,104,159,200}

FIGURE 5–34. A head computed tomography scan of a patient with mental status changes after carbon monoxide poisoning. The scan shows characteristic bilateral symmetrical lucencies of the globus pallidus (arrows). (Used with permission of Dr. Paul Blackburn, Maricopa Medical Center, AZ.)

Basal ganglion lucencies, white matter lesions, and atrophy are caused by other xenobiotics such as methanol,^{12,41,69,82,142,173} ethylene glycol, cyanide,^{58,139} hydrogen sulfide, inorganic and organic mercury,¹³¹ manganese,^{13,190} heroin,^{104,108} barbiturates, chemotherapeutic agents, solvents such as toluene,^{57,93,171,150,83,156} and podophyllin.^{28,144} Nontoxicologic disorders may cause similar imaging abnormalities, including hypoxia, hypoglycemia, and infectious encephalitis.^{82,88}

Nuclear Scintigraphy. Whereas both CT and MRI display cerebral anatomy, nuclear medicine studies provide functional information about the brain. Nuclear scintigraphy uses radioactive isotopes that are bound to carrier molecules (ligands). The choice of ligand depends on the biologic function being studied. Brain cells take up the radiolabeled ligand

in proportion to their physiologic activity or the regional blood flow. The radioactive emission from the isotope is detected by a scintigraphic camera, which produces an image showing the quantity and distribution of tracer. Better anatomic detail is provided by using CT techniques to generate cross-sectional images. There are two such technologies: SPECT and PET. These imaging modalities are used in the research and clinical settings to study the neurologic effects of particular xenobiotics and the mechanisms of xenobiotic-induced neurologic dysfunction.

SPECT uses conventional isotopes such as technetium-99m and iodine-123.¹¹⁵ These isotopes are bound to ligands that are taken up in the brain in proportion to regional blood flow, reflecting the local metabolic rate.

PET uses radioactive isotopes of biologic elements such as carbon-11, oxygen-15, nitrogen-13, and fluoride-18 (a substitute for hydrogen).¹⁵⁴ These radioisotopes have very short half-lives so that PET scanning requires an onsite cyclotron to produce the isotope. The isotopes are incorporated into molecules such as glucose, oxygen, water, various neurotransmitters, and drugs. Labeled glucose is taken up in proportion to the local metabolic rate for glucose. Uptake of labeled oxygen demonstrates the local metabolic rate for oxygen. Labeled neurotransmitters generate images reflecting their concentration and distribution within the brain.

Both PET and SPECT have been used to study the effects of various xenobiotics on cerebral function. For example, although both CT and MRI can detect cerebellar atrophy in individuals with chronic alcoholism, there is a poor correlation between the magnitude of cerebellar atrophy and the clinical signs of cerebellar dysfunction. PET scans may demonstrate diminished cerebellar metabolic rate for glucose, which correlates more accurately with the patient's clinical status.^{72,209}

In patients with severe neurologic dysfunction after carbon monoxide poisoning, SPECT regional blood flow measurements show diffuse hypometabolism in the frontal cortex.³⁰ In one patient, severe perfusion abnormalities improved slightly over several months in proportion to the patient's gradual clinical improvement.⁹⁸ In another patient treated with hyperbaric oxygen, a SPECT scan revealed increased blood flow in the frontal lobes, although the blood flow still remained significantly less than normal.¹²⁴

In patients who chronically use cocaine, SPECT blood flow scintigraphy demonstrates focal cortical perfusion defects. The extent of these perfusion defects correlates with the frequency of drug use. Focal perfusion defects probably represent local vasculitis or small areas of infarction.^{92,202} PET scanning has been used to demonstrate the effects of cocaine on cerebral blood flow and regional glucose metabolism. PET neurotransmitter studies show promise in elucidating potential mechanisms of action of cocaine. Using radiolabeled dopamine analogs, downregulation of dopamine (D₂) receptors has been noted after a cocaine binge. This finding may be responsible for cocaine craving that occurs during cocaine withdrawal. Using ¹¹C-labeled cocaine, uptake of cocaine can be demonstrated in the basal ganglia, a region rich in dopamine receptors.²⁰⁷

Much has been learned about these imaging modalities, and initial applications can be applied to patient care. These imaging modalities are capable of demonstrating abnormalities in many patients with xenobiotic exposures, although other patients with significant cerebral dysfunction have normal study findings.

SUMMARY

This chapter has highlighted a variety of situations in which diagnostic imaging studies are useful in toxicologic emergencies.

- Imaging can be an important tool in establishing a diagnosis, assisting in the treatment of patients, and detecting complications of a toxicologic emergency.
- The imaging modalities include plain radiography, CT, enteric and intravascular contrast studies, nuclear scintigraphy, and ultrasonography.
- However, effective use of a diagnostic test requires a precise understanding of the clinical situations in which each test can be useful, knowledge of the capabilities and limitations of the tests, and how the results should be applied to the care of an individual patient.

6 LABORATORY PRINCIPLES

Petrie M. Rainey

Toxicology addresses harm caused by acute and chronic exposures to excessive amounts of a xenobiotic. Detecting the presence or measuring the concentration of toxic xenobiotics is the primary activity of the analytical toxicology laboratory. Such testing is closely intertwined with therapeutic drug monitoring, in which drug concentrations are measured as an aid to optimizing drug dosing regimens. The toxicology laboratory is frequently viewed in much the same way as other clinical laboratories often are—as a “black box” that converts orders into test results. Because toxicology testing volumes are relatively low and menus are extensive, testing is not as highly automated as in other clinical laboratories. Many results may be “handmade the old-fashioned way.” A downside of this may be somewhat longer turnaround times. But the upside is that toxicology laboratory personnel have the incentive and flexibility to develop substantial expertise. Clinicians who understand how toxicology testing is done will be able to order more judiciously and apply the results more effectively.

RECOMMENDATIONS FOR ROUTINELY AVAILABLE TOXICOLOGY TESTS

Despite a common focus, there is remarkable variability in the range of tests offered by analytical toxicology laboratories. Test menus may range from once-daily testing for routinely monitored drugs and common drugs of abuse to around-the-clock availability of a broad array of assays with the theoretical potential to identify several thousand compounds. Consensus statements have recommended tests that should be available to support management of poisoned patients presenting to emergency departments.^{21,32} These guidelines make specific recommendations but recognize that no set of recommendations will be universally appropriate and that it is impossible for a clinical laboratory to offer a full spectrum of toxicology testing in real time.

Decisions on the menu of tests to be offered by any specific laboratory should be decided by the laboratory director in consultation with the medical toxicologists and other clinicians who will use the service and should take into account regional patterns of use of licit and illicit drugs and exposure to environmental toxins, as well as resources available and competing priorities.

The recommendations in [Table 6–1](#) were developed by the National Academy of Clinical Biochemists (NACB) from a consensus process that involved clinical biochemists, medical toxicologists, forensic toxicologists, and emergency physicians.³² Although these tests should be readily available in the clinical laboratory, they should not be considered as a test panel for possibly poisoned patients. As with all laboratory tests, they should be selectively ordered based on the patient’s history, clinical presentation, or other relevant factors. Suggested turnaround time for reporting serum concentrations of the drugs listed in [Table 6–1](#) was one hour or less. Quantitative tests for serum methanol and ethylene glycol were also recommended, with the reservations that these tests are not needed in all settings and that a realistic turnaround time is 2 to 4 hours. Serum cholinesterase testing with a turnaround time of less than 4 hours was proposed by some participants but did not achieve a general consensus. In the United Kingdom, the National Poisons Information Service and the Association of Clinical Biochemists have recommended a nearly identical list of tests, omitting the anticonvulsants.²¹

TABLE 6–1. Toxicology Assays Recommended by the National Academy of Clinical Biochemists

<i>Quantitative Serum Assays</i>	<i>Qualitative Urine Assays</i>
Acetaminophen (APAP)	Amphetamines
Carbamazepine	Barbiturates
Cooximetry (carboxyhemoglobin, methemoglobin, oxygen saturation)	Cocaine
Digoxin	Opiates
Ethanol	Propoxyphene
Iron (plus transferrin or iron-binding capacity)	Phencyclidine
Lithium	Tricyclic antidepressants (TCAs)
Phenobarbital	
Salicylates	
Theophylline	
Valproic acid	

Although the consensus for the menu of serum assays was generally excellent, there was less agreement as to the need for qualitative urine assays. This was largely a result of issues of poor sensitivity and specificity, poor correlation with clinical effects, and infrequent alteration of patient management. Although these were potential issues for all of the urine drug tests, they led to explicit omission of tests for tetrahydrocannabinol (THC) and benzodiazepines from the recommended list despite their widespread use. THC results were thought to have little value in managing patients with acute problems, and tests for benzodiazepines were believed to have an inadequate spectrum of detection. Testing for amphetamines, propoxyphene, and phencyclidine (PCP) were only recommended in areas where use was prevalent. It was also suggested that diagnosis of tricyclic antidepressant (TCA) toxicity not be based solely on the results of a urine screening immunoassay because a number of other drugs may cross-react. The significance of TCA results should always be correlated with electrocardiographic and clinical findings. The only urine test included in the United Kingdom guidelines was a spot test for paraquat.²¹ Paraquat testing was omitted in the NACB guidelines because of a very low incidence of paraquat exposure in North America.³²

The NACB guidelines also recommend the availability of broad-spectrum toxicology testing in addition to the tests in Table 6–1 to be used for selected patients with presentations compatible with poisoning but who remain undiagnosed and who are not improving. In general, such testing should not be ordered until the patient is stabilized and input has been obtained from a medical toxicologist or poison center. This second level of testing may be provided directly by the local laboratory or by referral to a reference laboratory or a regional toxicology center.

Many physicians order a broad-spectrum toxicology screen for a poisoned patient if one is readily available, but only approximately 2% of clinical laboratories provide relatively comprehensive toxicology services (as estimated from proficiency testing data³). Although broad-spectrum toxicology screens can identify most drugs present in overdosed patients, the results of broad-spectrum screens infrequently have altered management or outcomes.^{13,14,20,22,29}

The extent to which the NACB recommendations are being followed may be estimated from the numbers of laboratories participating in various types of proficiency testing. Result summaries from the 2011 series of proficiency surveys administered by the College of American Pathologists suggest that among laboratories that offer routine clinical testing, 50% to 60% offer quantitative assays for APAP, carbamazepine, ethanol, lithium, phenobarbital, salicylates, theophylline, and valproic acid; 60% to 70% offer digoxin, iron, and transferrin or iron-binding capacity; and 70% to 80% offer carboxyhemoglobin and methemoglobin. About half of these laboratories offer screening tests for drugs of abuse in urine.³

About 2% of laboratories participated in proficiency testing for a full range of toxicology services. These full-service laboratories typically offer quantitative assays for additional therapeutic drugs, particularly TCAs, as well as assays that are designated as broad-spectrum or comprehensive toxicology screens. About 80% of these full-service toxicology laboratories offer testing for volatile alcohols other than ethanol, and half offer testing for ethylene glycol.⁴

Although relatively few laboratories offer a wide range of in-house testing, most laboratories send out specimens to reference laboratories that offer large toxicology menus. The turnaround time for such “send-out” tests ranges from a few hours to several days, depending on the proximity of the reference laboratory and the type of test requested.

Even in full-service toxicology laboratories, the test menu may vary substantially from institution to institution. Larger laboratories typically offer one or more broad-spectrum testing choices, often referred to as “tox screens.” There is as much variety in the range of xenobiotics detected by various toxicologic screens as there is in the total menu of toxicologic tests. Routinely available tests are usually listed in a printed or online laboratory manual. Laboratories with comprehensive services may be able to offer ad hoc chromatographic assays for additional xenobiotics that are not listed. Testing that is sent to a reference laboratory is often not listed in the laboratory manual. The best way to determine if a particular

xenobiotic can be detected or quantitated is to ask the director or supervisor of the toxicology or clinical chemistry section because laboratory clerical staff may only be aware of tests listed in the manual.

USING THE TOXICOLOGY LABORATORY

There are many reasons for toxicologic testing. The most common function is to confirm or exclude suspected toxic exposures. A laboratory result provides a level of confidence not readily obtained otherwise and may avert other unproductive diagnostic investigations driven by the desire for completeness and medical certainty. Testing increased diagnostic certainty in more than half of cases,^{2,13,14} and in some instances, a diagnosis may be based primarily on the results of testing. This can be particularly important in poisonings with xenobiotics having delayed onset of clinical toxicity, such as APAP, or in patients with ingestion of multiple xenobiotics. In these instances, characteristic clinical findings may not have developed at the time of presentation or may be obscured or altered by the effects of coingestants.

Testing can provide two key parameters that will have a major impact on the clinical course, namely, the xenobiotic involved and the intensity of the exposure. This information can assist in triage decisions and can facilitate management decisions, such as use of specific antidotes or interventions to hasten elimination. Well-defined exposure information can also facilitate provision of optimum advice by poison centers. Finally, positive findings for ethanol or drugs of abuse in trauma patients may serve as an indication for substance use intervention as well as a risk marker for the likelihood of future trauma.¹³

The confirmation of a clinical diagnosis of poisoning provides an important feedback function, whereby the physician may evaluate the diagnosis against a “gold standard.” Another important benefit is reassurance that an unintentional ingestion did not result in absorption of a toxic amount of xenobiotic. This reassurance may allow a physician to avoid spending excessive time with patients who are relatively stable. It may also allow admissions to be made and interventions undertaken more confidently and efficiently than would be likely based solely on a clinical diagnosis. Testing may also be indicated for medicolegal reasons to establish a diagnosis “beyond a reasonable doubt.”

The key to optimal use of the toxicology laboratory is communication. This begins with learning the laboratory’s capabilities, including the xenobiotics on its menus, which can be quantitated and which merely detected, and the anticipated turnaround times. For screening assays, one should know which xenobiotics are routinely detected, which ones can be detected if specifically requested, and which ones cannot be detected even when present at concentrations that typically result in toxicity.

One should know specimen type that is appropriate for the test requested. A general rule is that quantitative tests require serum (red stopper) or heparinized plasma (green stopper) but not ethylenediamine tetraacetic acid (EDTA) plasma (lavender stopper) or citrate plasma (light-blue stopper). EDTA and citrate bind divalent cations that may serve as cofactors for enzymes used as reagents or labels in various assays. Additionally, liquid EDTA and citrate anticoagulants dilute the specimen. Serum or plasma separator tubes (identifiable by the separator gel at the bottom of the tube) are also acceptable, provided that prolonged gel contact before testing is avoided. Some hydrophobic drugs may diffuse slowly into the gel, leading to falsely low results after several hours. A random, clean urine specimen is generally preferred for toxicology screens because the higher drug concentrations usually found in urine can compensate for the lower sensitivity of the broadly focused screening techniques. A urine specimen of 20 mL is usually optimal. Requirements for all specimens may vary from laboratory to laboratory.

When requesting a screening test, an important—and often overlooked—item of communication is specifying any xenobiotics of particular concern. This may allow faster results and a greater likelihood of detection.

Most full-service toxicology laboratories welcome consultation on puzzling cases or results that appear inconsistent with the clinical presentation. The laboratory will be familiar with the capabilities and limitations of their testing methods, as well as common sources of discrepant results.

METHODS USED IN THE TOXICOLOGY LABORATORY

Most tests in the toxicology laboratory are directed toward the identification or quantitation of xenobiotics. The primary techniques used include spot tests, spectrochemical tests, immunoassays, and chromatographic techniques. Mass spectrometry may also be used, usually in conjunction with gas chromatography (GS) or liquid chromatography. [Table 6–2](#) compares the basic features of these methodologies. Other methodologies include ion-selective electrode measurements of lithium, atomic absorption spectroscopy or inductively coupled plasma mass spectroscopy for lithium and heavy metals, and anodic stripping methods for heavy metals. Many adjunctive tests, including glucose, creatinine, electrolytes, osmolality, metabolic products, and enzyme activities, may also be useful in the management of poisoned patients. The focus here is on the major methods used for directly measuring xenobiotics.

TABLE 6–2. Relative Comparison of Toxicology Methods

Method	Sensitivity	Specificity	Quantitation	Analyte Range	Speed	Cost
Spot test	+	±	No	Few	Fast	\$
Spectrochemical	+	+	Yes	Few	Medium	\$
Immunoassay	++	++	Yes	Moderate	Variable	\$\$
TLC	+	++	No	Broad	Slow	\$\$
HPLC	++	++	Yes	Broad	Medium	\$\$
GC	++	++	Yes	Broad	Medium	\$\$
GC/MS	+++	+++	Yes	Broad	Slow	\$\$\$
LC/MS/MS	+++	+++	Yes	Broad	Medium	\$\$\$\$

\$ = very low; \$\$\$\$ = very high cost; GC = gas chromatography; GC/MS = gas chromatography/mass spectroscopy; HPLC = high-performance liquid chromatography; LC/MS/MS = liquid chromatography/tandem mass spectroscopy; TLC = thin-layer chromatography.

Spot Tests

The simplest tests are spot tests. These rely on the rapid reaction of a xenobiotic with a chemical reagent to produce a colored product (eg, the formation of a colored complex between salicylate and ferric ions) that is visually assessed in a semiquantitative manner. Because the reagents may cause precipitation of serum proteins, spot tests are more commonly performed on urine specimens or gastric aspirates. Such tests were once a mainstay of toxicologic testing. Because of the poor selectivity of chemical reagents, as well as substantial variability in visual interpretation, these assays suffer from fairly frequent false-positive results and occasional false-negative results and are rarely used today.

Spectrochemical Tests

Spectrochemical tests rely on measurement of a light-absorbing substance. Some analytes that are intrinsically light absorbing may be directly measured. Cooximetry (also known as hemoximetry) represents a sophisticated application of spectrophotometry to the measurement of various forms of hemoglobin in a hemolyzed blood sample. Measurement of light absorbance at multiple wavelengths allows several hemoglobin species to be simultaneously quantitated. For mathematical reasons, the number of wavelengths used must be greater than the number of different types of hemoglobin present. This is why classic pulse oximetry, which uses only two wavelengths, yields spurious results in the presence of significant amounts of methemoglobin or carboxyhemoglobin ([Chaps. 29, 125, and 127](#)). Cooximetry is relatively free of interferences because the concentrations of the hemoglobins are so much higher than other substances in the blood. However, the presence of intensely colored substances (eg, methylene blue) may cause spurious increases or decreases in the apparent percentages of the hemoglobins. Modern instruments are often able to recognize a significantly atypical pattern of absorbance and generate an error message in addition to or instead of a result.

Most analytes are neither as deeply colored nor as highly concentrated as hemoglobin species. Their detection requires a chemical reaction to produce an intensely light-absorbing product that is quantitatively measured at a specific wavelength in a spectrophotometer. Because spectrophotometers can also measure ultraviolet and infrared light, it is not necessary for the product to have a visible color. Early spectrochemical assays typically measured the absorbance after conversion of all of the analyte to the light-absorbing product. Modern assays usually use rate spectrophotometry, taking multiple absorbance measurements over time to determine the rate of change in light absorbance as the reaction proceeds. During the initial phase of the reaction, this rate is constant and proportional to the initial concentration of the analyte. This significantly reduces the time needed to obtain a result because it is not necessary for the reaction to go to completion, and it allows the averaging of multiple measurements, improving precision. Furthermore, it is unaffected by nonreacting substances that absorb light at the test wavelength because the absorbance of the nonreacting substances is constant and does not contribute to the rate of change in the absorbance.

Rate spectrophotometry remains subject to interference by substances that react to produce light-absorbing products, thereby falsely increasing the apparent concentration. Substances that inhibit the assay reaction or that consume reagents without producing a light-absorbing product give falsely low results. For example, ascorbic acid produces negative interference in many spectrophotometric assays that use oxidation reactions to generate colored products.

One way to improve the selectivity of a spectrochemical assay is to increase the selectivity of the reaction that generates the light-absorbing product. Enzymes, which can catalyze highly selective reactions, are often used for this purpose. For example, many assays for ethanol use alcohol dehydrogenase (ADH) to catalyze the oxidation of ethanol to acetaldehyde, with concomitant reduction of the cofactor NAD⁺ (oxidized form of nicotinamide adenine dinucleotide) to NADH (reduced form of nicotinamide adenine dinucleotide). The initial rate of increase in light absorption produced by

the conversion of NAD^+ to NADH is proportional to the concentration of ethanol. Although other alcohols, such as isopropanol and methanol, can also be oxidized by ADH, they are much poorer substrates for ADH with low rates of reaction and correspondingly low levels of interference.

Many other enzymatic assays also rely on measuring the change in light absorption at 340 nm when NAD^+ is converted to NADH or vice versa. These include enzymatic assays for ethylene glycol, as well as some enzyme-linked immunoassays, such as EMIT (enzyme-multiplied immunoassay technique) assays. All such assays are potentially subject to interference by specimens with high concentrations of lactate. Lactate dehydrogenase, which is naturally present in serum, will oxidize this lactate to pyruvate if NAD^+ becomes available for simultaneous reduction to NADH. When a serum specimen with high lactate is mixed with assay reagents that contain NAD^+ , oxidation of the lactate contributes to the total rate of NADH production. The increased rate of NADH production results in a false increase in the measured concentration of the target analyte.

Some enzymatic reactions do not produce a colored product. Enzymes such as glucose oxidase or lactate oxidase couple oxidation of the substrate to reduction of oxygen to hydrogen peroxide, which is colorless. A coupled second reaction is then necessary using the peroxide to convert a colorless dye to a colored one. Oxidase-based reactions may be subject to interference by compounds with high structural similarity to the target analyte. For example, glycolate, a toxic metabolite of ethylene glycol, is an excellent substrate for lactate oxidase and will give falsely high lactate results when it is present.

Immunoassays

The need to measure very low concentrations of an analyte with a high degree of specificity led to the development of immunoassays. The combination of high affinity and high selectivity makes antibodies excellent assay reagents. There are two common types of immunoassays: noncompetitive and competitive. In noncompetitive immunoassays, the analyte is sandwiched between two antibodies, each of which recognizes a different epitope on the analyte. In competitive immunoassays, analyte from the patient's specimen competes for a limited number of antibody binding sites with a labeled version of the analyte provided in the reaction mixture. Because most drugs are too small to have two distinct antibody binding sites, drug immunoassays are usually competitive.

In competitive immunoassays, increasing the concentration of xenobiotic in the specimen results in increased displacement of labeled xenobiotic from the antibodies. The amount of xenobiotic in the specimen can be determined by measuring either the amount of label remaining bound to the assay antibodies or the amount of label free in solution. In the earliest immunoassays, the label was a radioisotope, typically iodine-125, tritium, or carbon-14. Today, radioimmunoassays are relatively uncommon because of problems associated with handling and disposal of radioactivity. Nonisotopic immunoassays are currently the most widely used methodologies for the measurement of drugs. They offer high selectivity and good precision and are readily adapted to automated analyzers, thereby decreasing both the cost and the turnaround time of the assays. The xenobiotics for which immunoassays are available are limited to those for which there is a high demand, such as widely monitored therapeutic drugs and the drugs of abuse included in workplace drug screening. However, because production costs are relatively low, these tests are widely distributed at reasonable prices.

The most widely used nonisotopic drug immunoassays are in the category of homogenous immunoassays. Homogenous immunoassays measure differences in the properties of bound and free labels rather than directly measuring one or the other after their physical separation. Avoiding a separation step allows homogenous immunoassays to be readily adapted to automated analysis. Homogenous techniques that are in wide use include EMIT (Fig. 6-1), kinetic inhibition of microparticles in solution (KIMS), and cloned enzyme donor immunoassay (CEDIA).

FIGURE 6–1. Enzyme-multiplied immunoassay technique (EMIT) immunoassay. The drug to be measured is labeled by being attached to the enzyme glucose-6-phosphate dehydrogenase (G6PD) near the active site. **(A)** Binding of the enzyme-labeled drug to the assay antibody blocks the active site, inhibiting conversion of NAD^+ (oxidized form of nicotinamide adenine dinucleotide) to NADH (reduced form of nicotinamide adenine dinucleotide). **(B)** Unlabeled drug from the specimen can displace the drug–enzyme conjugate from the antibody, thereby unblocking the active site and increasing the rate of reaction.

Many of the newest automated immunoassays are again using physical separation techniques. In these assays, the detection antibody is physically attached to a solid support, and separation occurs by a simple wash step. This wash step removes the patient's serum along with many potentially interfering substances. Older assays of this type used antibodies bound to large plastic beads or wells of microtiter plates and required long incubation steps because of substantial times required for diffusion of the reactants to the antibodies. Newer assays typically use latex microparticles that have very high total surface areas, allowing rapid equilibration and short assay times.

Figure 6–2 shows a schematic magnetic microparticle enzyme-labeled chemiluminescent competitive immunoassay. A single enzyme label can generate many photons, allowing high signal amplification. Coupled with a background luminescence that is essentially zero, such assays can measure concentrations below the nanomolar level. Many variations of this approach are in use. Enzyme substrates may be used that result in fluorescent or colored products. Enzymes other than alkaline phosphatase may be used as labels, or nonenzymatic fluorescent, chemiluminescent, or electroluminescent labels may be used. These new techniques are readily automated and have higher sensitivities than homogenous immunoassays.

FIGURE 6–2. Magnetic microparticle chemiluminescent competitive immunoassay. **(A)** Unlabeled drug from the specimen competes with alkaline phosphatase–labeled drug for binding to antibody-coated magnetic microparticles. The microparticles are then held by a magnetic field while unbound material is washed away. **(B)** A dioxetane phosphate derivative is added and is dephosphorylated by microparticle-bound alkaline phosphatase to give an unstable dioxetane product that spontaneously decomposes with emission of light. The rate of light production is directly proportional to the amount of alkaline phosphatase bound to the microparticles and inversely proportional to the concentration of competing unlabeled drug from the specimen.

Microparticle capture assays are a type of qualitative competitive immunoassay that have become very popular, especially for urine drug screening tests. The use of either colored latex or colloidal gold microparticles enables the result to be read visually as the presence or absence of a colored band, with no special instrumentation required. Competitive binding occurs as the assay mixture is drawn by capillary action through a porous membrane. This design feature is responsible for alternate names for the technique: lateral flow immunoassay or immunochromatography.

The simplest microparticle capture design uses an antidrug antibody bound to colored microparticles and a capture zone consisting of immobilized drug (Fig. 6–3). If the specimen is xenobiotic free, the beads will bind to the immobilized analyte, forming a colored band. When the amount of drug in the patient specimen exceeds the detection limit, all of the antibody sites will be occupied by drug from the specimen, and no labeled antibody will be retained in the capture zone. The use of multiple antibodies and discrete capture zones with different immobilized analytes can allow several xenobiotics to be detected with a single device.

FIGURE 6-3. Microparticle capture immunoassay. (A) Diagram of a device before specimen addition. Colored microbeads (about the size of red blood cells) coated with antidrug antibodies (Y) are in the specimen well. At the far end of a porous strip are capture zones with immobilized drug molecules (•) and a control zone with antibodies recognizing the antibodies that coat the microbeads. (B) Adding the urine specimen suspends the microbeads, which are drawn by capillary action through the porous strip and into an absorbent reservoir (hatched area) at the far end of the strip. In the absence of drug in the urine, the antibodies will bind the beads to the capture zone containing the immobilized drug and form a colored band. Excess beads will be bound by antibody–antibody interactions in the control zone, forming a second colored band that verifies the integrity of the antibodies in the device. (C) If the urine contains the drug (•) in concentrations exceeding the detection limit, all of the antibodies on the microbeads will be occupied by drug from the specimen, and the microbeads will not be retained by the immobilized drug in the capture zone. No colored band will form. However, the beads will be bound and form a band in the control zone.

A disadvantage of this design is the potential for causing confusion because a positive test result is indicated by the absence of a band. More complex (and more expensive) variations have been developed in which a colored band denotes a positive test result.

Although immunoassays have a high degree of sensitivity and selectivity, they are also subject to interferences and problems with cross-reactivity. Cross-reactivity refers to the ability of the assay antibody to bind to xenobiotics other than the target analyte. Xenobiotics with similar chemical structures may be efficiently bound, which can lead to falsely elevated results. In some situations, cross-reactivity can be beneficially exploited. For example, some immunoassays effectively detect classes of drugs rather than one specific drug. Immunoassays for opioids use antibodies to morphine that cross-react to varying degrees with structurally related substances, including codeine, hydrocodone, and hydromorphone. Oxycodone typically has low cross-reactivity, and higher concentrations are required to give a positive result. The cross-reactivity of non-morphine opiates varies with manufacturer. Consult with your lab for the relative sensitivities of the immunoassay it uses. Structurally unrelated synthetic opioids, such as meperidine and methadone, have little or no cross-reactivity and are not detected by opiate immunoassays. Immunoassays for the benzodiazepine class react with a wide variety of benzodiazepines but with varying degrees of sensitivity.^{12,16} Because of the highly variable response of immunoassays to the various opiates and benzodiazepines, methods based on mass spectrometry should be used for definitive results.

Class specificity can be a two-edged sword. Assays for the TCA family have similar reactivity with amitriptyline, nortriptyline, imipramine, and desipramine and can be used to provide an estimate of the total concentration of any combination of these drugs. To account for nonuniform cross-reactivity, such results of these assays are usually reported as concentration ranges (eg, <100 ng/mL, 100–300 ng/mL). A large number of other drugs with tricyclic structures, including carbamazepine, many phenothiazines, and diphenhydramine, also cross-react and generate a signal, particularly at concentrations found in patients who overdose. Qualitative tests, such as microparticle capture assays, may then yield false-positive results if the signal generated by the cross-reacting drug (eg, carbamazepine) exceeds the detection limit of the immunoassay. With quantitative or semiquantitative assays, however, the apparent concentration produced by a cross-reacting drug is generally well below TCA concentrations associated with toxicity.

Even when an antibody is selected to be specific to a single drug, it is common that metabolites of the target drug show some cross-reactivity. This, too, may be beneficial. When the metabolite is an active one (eg, carbamazepine epoxide), the contribution of its cross-reactivity may yield results that correlate better with the drug effect than the true concentration of the parent drug alone.

Immunoassays are also subject to interference by substances that impair detection of the label. Elevated lactate concentrations may lead to spuriously increased drug concentrations in specimens tested by EMIT, as described earlier. Immunoassays that rely on enzyme labels are particularly sensitive to nonspecific interference because enzyme activity is highly dependent on reaction conditions. A number of substances that can inhibit the enzyme reaction in EMIT assays are used to adulterate urine submitted for drug abuse testing with the intent of producing false-negative results (see the discussion of drug-abuse screening tests under “Special Considerations for Drug Abuse Screening Tests” later). Such adulteration may be detected when the rate of reaction is lower than the rate observed with a drug-free control.

Chromatography

Chromatography encompasses several related techniques in which analyte specificity is achieved by physical separation. The unifying mechanism for separation is the partition of the analytes between a stationary phase and a moving phase (mobile phase). In most instances, the stationary phase consists of very fine particles arranged in a thin layer or enclosed within a column. The mobile phase flows through the spaces between the particles. Analytes are in a rapid equilibrium between solution in the mobile phase and adsorption to the surfaces of the particles. They move when in the mobile phase and stop when adsorbed to the stationary phase. The average velocity of the analyte xenobiotics depends on the relative time spent in the moving versus stationary phase. Xenobiotics that partition primarily into the mobile phase have average velocities slightly lower than the mobile phase velocity. Average velocity decreases as the proportion of time adsorbed to the stationary phase increases. Under controlled conditions, these average velocities are highly reproducible. Xenobiotics

may be provisionally identified based on their characteristic velocity, as measured by the amount of time required to traverse the length of a chromatography column (retention time). Chromatography is a separation method and must be combined with a detection method to allow identification and measurement of the separated substances.

Chromatographic behavior is sufficiently reproducible that the failure to detect a signal at the retention time characteristic of a compound effectively excludes the presence of that compound in amounts greater than the detection limit. On the other hand, a number of different substances may have migration velocities that are identical or nearly so. A positive finding is therefore not completely specific. Definitive identification depends on having additional information, which may be obtained through selective detection techniques or by confirmatory testing using a second method. The sensitivity of chromatographic methods depends on both the amount of specimen available and the sensitivity of the detection method. A major advantage of chromatographic techniques is that multiple xenobiotics may be detected and measured in a single procedure. Nor is it necessary to know in advance the specific xenobiotic to be looked for. For this reason, chromatographic techniques have a major role in screening for multiple xenobiotics.

Most chromatographic procedures require extraction and concentration of the xenobiotics to be analyzed before the chromatography is done. Extraction results in removal of salts, proteins, and other materials that may exhibit unfavorable interactions with either of the chromatographic phases. Concentration allows the substances to be introduced in a narrow “band,” so that compounds with slightly different relative mobilities become completely resolved, or separated from one another, rather than overlapping. This also results in a more intense signal as a band passes through the detector and increases sensitivity.

Extraction of drugs is most commonly done with organic solvents, but “solid-phase extraction” is also very popular.¹¹ Solid-phase extraction is itself a modified chromatographic procedure in which a urine or serum specimen is passed through a short chromatography column with a hydrophobic stationary phase. Most drugs are sufficiently hydrophobic to partition almost completely into the stationary phase and are retained on the column. Subsequently, the retained xenobiotics are eluted with an organic solvent. The organic solvents from either extraction technique are evaporated to concentrate the extract. The extraction process allows the analyte from a large volume of specimen to be concentrated. Detection sensitivity can thereby be increased provided large-volume specimens can be readily obtained, as is true with urine.

Often a preextraction treatment is used to increase the hydrophobicity of the substances to be extracted. The most common manipulation is pH adjustment, either upward or downward, to convert charged forms of drugs into uncharged, hydrophobic, and therefore extractable ones. In other instances, enzymatic or chemical hydrolysis may be used to convert water-soluble glucuronide metabolites back to their more readily extracted parent compounds, for example, conversion of morphine glucuronide to morphine.

In the technique of high-performance liquid chromatography (HPLC), a stationary phase is packed into a column and the mobile phase is pumped through under high pressure (Fig. 6–4). This allows good flow rates to be achieved even when solid phases with very small particle sizes are used. Smaller particle size increases surface area, decreases diffusion distances, and improves resolution, but the spaces between the particles are also smaller, increasing the resistance to flow. The use of high pressure and small particles allows good separations while keeping assay time short.

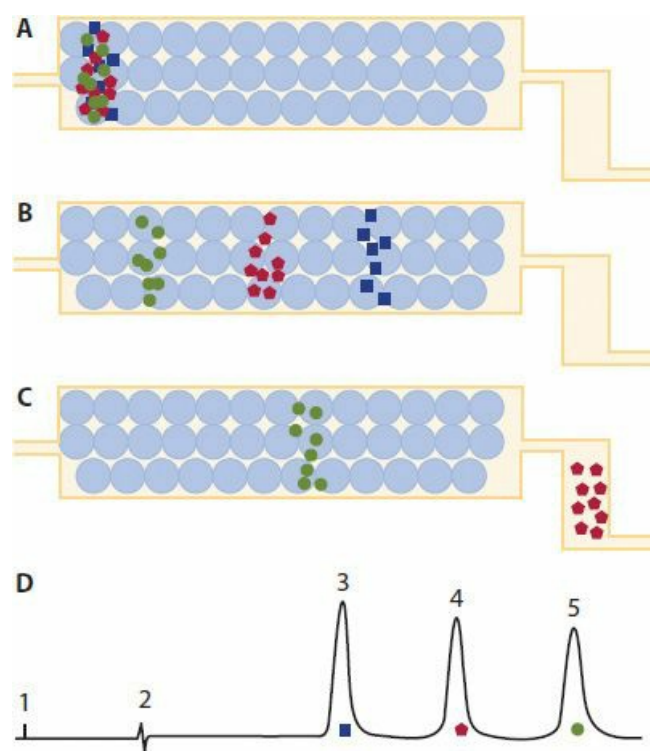

FIGURE 6–4. High-performance liquid chromatography (HPLC). HPLC is schematically shown. (A) A mixture of three compounds (■) (●) (●) is injected into a column filled with a spherical reversed-phase packing. (B) The compounds move

through the column at characteristic speeds. The most hydrophilic compound (■) moves most quickly, and the most hydrophobic compound (●) moves most slowly. (C) The compound of intermediate polarity (●) has reached the detection cell, where it absorbs light directed through the cell and generates a signal proportional to its concentration. (D) Illustration of the HPLC tracing that might result: 1 indicates the time of injection. The artifact at 2 results when the injection solvent reaches the detector and indicates the retention time of a completely unretained compound. The peaks at 3, 4, and 5 correspond to the separated compounds. For example, peak 4 might be amitriptyline, peak 3 might be the more polar metabolite, nortriptyline, and peak 5 could be the more hydrophobic internal standard N-ethylnortriptyline. Later-emerging peaks are typically wider and shorter because of more time for diffusive forces to spread out the molecules

HPLC drug assays typically use “reverse-phase” chromatography. Early chromatographic techniques typically used relatively polar silica gel particles as the stationary phase, with organic solvent mobile phases. Reverse-phase chromatography uses stationary phases consisting of silica gel particles that have had hydrocarbon molecules covalently linked to the outer surface. This coats the particles with a permanently bonded oil-like layer. Mobile phases are primarily aqueous with varying amounts of organic solvent. Because of these modifications, hydrophobic xenobiotics are more strongly adsorbed by the stationary phase, but hydrophilic ones tend to remain in the mobile phase. This results in an order of elution from the column that is approximately the reverse of that seen with unmodified silica gel and organic solvents. Thus, the term reverse-phase chromatography is used. HPLC can be done using either “normal-phase” or “reverse-phase” conditions, but reverse-phase conditions are much more commonly used. A variety of hydrocarbons can be used to derivatize the silica gel. By far, the most common reverse-phase columns use an octadecyl hydrocarbon as the outer coating and are often referred to as C-18 columns.

In HPLC, the xenobiotics are detected after they exit the chromatographic column. In this case, they are identified by their retention time (the characteristic time required to traverse the column). Because most xenobiotics absorb ultraviolet light, detection is commonly by ultraviolet spectroscopy using specially designed flow-through cuvettes. Measuring light absorbance at a selected wavelength allows the amount of the xenobiotic to be determined. Accuracy is often enhanced by comparing the absorbance of the target analyte with absorbance of an internal standard (ie, a compound with a different retention time that is added in a fixed amount to all specimens). The ratio of the drug absorbance to the internal standard absorbance is proportional to the drug concentration in the specimen.

Although most HPLC detectors allow a selection of the detection wavelength, only one wavelength is commonly used during a given run. Some detectors, however, allow absorbance at multiple wavelengths to be determined by breaking white light into its component wavelengths after it has passed through the detection cuvette and then making measurements at multiple wavelengths simultaneously using a light-sensitive chip similar to those used in digital cameras. This allows the absorbance spectrum of a compound to be determined as it elutes from the column. This information can supplement the retention time and allow more specific identifications to be made.

HPLC is often the method of choice for measuring serum concentrations of xenobiotics for which no immunoassay is available. However, it is limited by an inability to analyze drugs with a wide range of polarities in a single assay or to fully resolve substances with very similar polarity, both of which limit its usefulness as a broad drug-screening technique.

GC is similar in principle to HPLC except that the moving phase is a gas, usually the inert gas helium but occasionally nitrogen. The schematic illustration of HPLC in Fig. 6–4 is also applicable to GC. The low flow resistance of gas allows high flow rates that make possible substantially longer columns than are used in HPLC. This offers the dual advantages of high resolution and fast analysis. As was true in HPLC, most GC assays incorporate an internal standard to increase precision.

Because the inert carrier gas does not engage in intermolecular interactions, partition of the analytes into the moving gas phase depends primarily on their natural volatility. Elevated column temperatures are required to achieve sufficient volatility for analysis of most xenobiotics. The use of a temperature gradient (the column temperature is programmed to increase throughout the course of the analysis) can allow xenobiotics with a wide range of volatility to be analyzed in a single run. This feature, coupled with excellent resolution, makes GC suitable for screening assays that encompass a broad range of drugs.

GC is limited to xenobiotics that are reasonably volatile at temperatures below 572°F (300°C), above which the stationary phase may begin to break down. Two principal attributes of a xenobiotic limit its volatility: its size and its ability to form hydrogen bonds. Xenobiotics that form hydrogen bonds via amino, hydroxyl, and carboxylate moieties can be made more volatile by replacing hydrogens on oxygen and nitrogen atoms with a nonbonding, preferably large, substituent. (Large substituents sterically hinder access to the acceptor electron pairs on the nitrogen and oxygen atoms.) A number of derivatizing agents can be used to add appropriate substituents. The most common derivatives involve the trimethylsilyl (TMS) group. Although derivatization with TMS substantially increases the molecular weight, the resulting derivative is much more volatile as a consequence of the loss of hydrogen bonding.

In traditional packed-column GC, the packing may consist of inert support particles with a thin coating of nonvolatile, high-molecular-weight oil that comprises the stationary phase. It is increasingly common for the stationary phase to be covalently bonded to the support particles. A highly useful variant of GC is capillary chromatography. A long, thin capillary tube of fused silica is coated on the inside with a covalently bonded stationary phase. The mobile gas phase flows

through the tiny channel in the middle. These capillaries are flexible, allowing very long columns (≥ 10 m) to be coiled into a small space. The long column length, coupled with highly uniform conditions throughout the column, results in extremely high resolution. The small diameter of the column allows rapid thermal equilibration and the use of steep temperature gradients that can speed analysis. The major drawback to capillary chromatography is a very limited column capacity. Special techniques are needed to restrict the amount of material introduced into the column and thereby to avoid overloading it. High-sensitivity detectors are required to measure the small quantities that can be chromatographed.

A number of detectors are available for GC. The most common detector, particularly for packed columns, is the flame ionization detector. This involves directing the outflow of the column into a hydrogen flame. Organic molecules emerging from the column are burned, creating charged combustion intermediates that can be measured as a current. The amount of current flow is largely determined by the mass of carbon that is being burned. Nitrogen–phosphorus detectors are also widely used in drug analysis. In this modification of a flame ionization detector, a heated bead coated with an alkali metal salt is used to selectively generate ions from xenobiotics containing nitrogen or phosphorus. These devices detect broad ranges of substances but do not identify them. The identity of the compounds detected must be inferred from the retention time.

The mass spectrometer can serve as a highly sensitive GC detector and possesses the ability to generate highly characteristic mass spectra from the compounds it is detecting. A special requirement of the mass spectrometer is that it requires a high vacuum to prevent the ionic particles that it creates from interacting with other molecules or ions. This requires removal of the inert carrier gas and is easiest when there is a low total gas flow, such as occurs with capillary GC. The mass spectrometer in turn provides good sensitivity for the small amounts of analyte that can be accommodated in capillary GC.

The detection process begins by generating ions from the analyte. This is usually done using electron impact ionization. The gas phase analyte is separated from the bulk of the carrier gas and introduced into an ionization chamber, where it is bombarded by a stream of electrons. Electron impact can dislodge an electron from the analyte, creating a positively charged ion and frequently imparting sufficient energy to the ion to break it into pieces. If fragmentation occurs, conservation of charge requires that one of the resulting fragments be a positively charged ion. The fragments into which a molecular ion can break are characteristic of the xenobiotic as are the relative probabilities that any given fragment will carry the positive charge.

The mass spectrometer then uses electromagnetic filtering to direct only ions of a specified mass-to-charge (m/z) ratio to a detector. Because most of the ions produced have a single positive charge, the observed peaks generally correspond to the mass of the ions. The detector has sufficient electronic amplification that a single ion could theoretically be detected, accounting for the high sensitivity of mass spectrometric detection. By rapidly scanning through a range of masses that are sequentially allowed to reach the detector, a mass spectrum may be generated. The mass spectrum records the masses of the pieces produced by fragmentation of the parent ion, as well as the relative frequency with which these fragments are produced and detected. The highest mass observed in the spectrum usually corresponds to the mass of intact parent ions generated from collisions that were not energetic enough to cause fragmentation.

Figure 6–5 shows the mass spectrum obtained from a gas chromatograph at a time when the TMS derivative of the cocaine metabolite benzoylecgonine was emerging from the capillary column. The mass spectrum of any compound is highly distinctive and usually unique. The primary exception involves optical enantiomers, both of which have the same mass spectrum. Toxicologically significant examples of enantiomers include D-methamphetamine, a drug of abuse, and L-methamphetamine, which is found in decongestant inhalers. It is also important to distinguish dextrophan, the major metabolite of the cough suppressant dextromethorphan, and levorphan (levorphanol), a controlled substance.

FIGURE 6-5. Mass spectrum of the trimethylsilyl derivative of benzoyllecgonine (TMS-BE). (A) Mass spectrum of effluent from a gas chromatography (GC) column at the retention time of TMS-BE. The unfragmented parent ion of TMS-BE is at a mass-to-charge (m/z) ratio of 361. The two fragment peaks at m/z 243 and 259 result from fracture of the bonds at X and Y, respectively, in structure of TMS-BE (inset in B). Additional peaks at m/z 243, 259, and 364 are derived from trideuterated TMS-BZE (d_3 -TMS-BE) added as an internal standard. The mass spectrometer can identify and quantify TMS-BE and d_3 -TMS-BE independently of one another by measuring the heights of the peaks unique for each compound. The peak at m/z 425 is from a coeluting contaminant. (B) Mass spectrum of pure TMS-BE.

To avoid the need to scan the full range of masses in a typical mass spectrum, selected ion monitoring is often used. Here, the mass spectrometer is typically programmed to filter and detect only three of the larger and more characteristic peaks in the mass spectrum. In the case of TMS-benzoyllecgonine (TMS-BE), the peaks at m/z 240, 256, and 361 are used. The concentration of TMS-BE in the specimen is determined from the ratio of the peak height at m/z 240 to height of a peak at m/z 243 that results from a corresponding fragment of the internal standard, which is TMS-BE that is labeled with three deuterium atoms (d_3 -TMS-BE) to give it a mass distinct from that of TMS-BE from the specimen (Fig. 6-5). The specificity of the identification is verified by finding peaks at m/z 256 and m/z 361, with peak height ratios to the peak at m/z 240 comparable to the ratios seen with authentic TMS-BE. The detection at the correct retention time of a xenobiotic producing all three peaks in the correct ratios produces an extremely specific identification.

The high sensitivity and specificity afforded by GS/mass spectrometry is being further extended by the related hybrid technique of liquid chromatography/tandem mass spectrometry, often abbreviated as LC/MS/MS.¹⁸ This technique is being

used in an increasing number of toxicology laboratories. In LC/MS/MS, a tandem mass spectrometer is used as the detector for liquid chromatography system. The initial ionization is done under conditions that do not promote fragmentation and is commonly achieved by adding or removing a proton rather than forcefully dislodging an electron. The resulting ions have a mass that differs from that of the parent molecule by one mass unit ($[M+H]^+$ or $[M-H]^-$). The first mass spectrometer is used to selectively filter only unfragmented ions with the expected molecular mass. As the selected ions exit the first mass spectrometer at high speed, they are allowed to collide with molecules of an inert gas. These collisions cause the ions to break apart to create the fragment mass spectrum that is detected by the second mass spectrometer. The additional selection step provided by the first mass spectrometer greatly enhances specificity and reduces background signal, enhancing sensitivity.

QUANTITATIVE DRUG MEASUREMENTS

When properly used to guide dosing adjustments, drug concentration measurements improve medical outcomes.⁹ However, many therapeutic drug measurements are drawn at inappropriate times or are made without an appropriate therapeutic question in mind. An essential requirement for interpretation of xenobiotic concentrations is that the relationship between concentrations and effects must be known. Such knowledge is available for routinely monitored xenobiotics and is often encapsulated in published ranges of therapeutic concentrations and toxic concentrations. Concentrations designated as “toxic” are usually higher than the upper end of the therapeutic range and typically represent concentrations at which toxicity is acute and potentially serious (see back cover).

For most xenobiotics, the relationships between toxic concentrations and effects cannot be systematically studied in humans and consequently are often incompletely defined. These relationships are largely inferred from data provided in overdose case reports and case series. The measurement of xenobiotic concentrations in overdose cases in which concentration–effect relationships are not well defined may contribute more to the management of future overdosed patients than to the management of the patient in whom the measurements were made.

For toxicologists, xenobiotic concentrations are especially useful in two ways. For xenobiotics whose toxicity is delayed or is clinically inapparent during the early phases of an overdose, concentrations may have substantial prognostic value and facilitate anticipatory management. These concentrations may also be used to make decisions regarding the use of antidotes or of interventions to hasten drug elimination, such as hemodialysis.

Quantitative xenobiotic measurements are subject to various interferences, but these are less problematic than in qualitative assays. Signals generated by cross-reacting substances are weaker than those from the target analyte and are relatively unlikely to lead to a false diagnosis of toxicity, particularly if the target analyte is absent. Such cross-reactivity can be exploited in some instances to provide confirmatory evidence of a poison for which no specific assay is immediately available. For example, the immunoassay finding of apparent subtoxic concentrations of TCAs can help confirm a diphenhydramine overdose, and the finding of a measurable digoxin concentration in an unexposed patient may suggest poisoning with other cardioactive steroids of plant or animal origin. Negative interferences are much less frequent. Interferences in chromatographic methods usually result from the presence of other compounds with migration rates similar to the target analyte. Because the migration rates are rarely exactly the same, the laboratory can often recognize the presence of the interference as an overlapping peak when both compounds are present. In such instances, the interference may impair accurate measurement of the drug concentration. When no target xenobiotic is present, misidentification of the interfering peak as the target becomes much more likely because a single peak is seen at approximately the expected position. Because interferences in chromatographic methods are generally unique to a specific method, information about these interferences should be obtained by asking the laboratory.

Xenobiotic measurements are unlike most other laboratory measurements in that the concentrations are highly dependent on the timing of the measurement. Knowledge of the pharmacokinetics of a xenobiotic can substantially enhance the ability to draw meaningful conclusions from a measured concentration. Some xenobiotics alter their pharmacokinetic behavior at very high concentrations. These changes in pharmacokinetics may be predictable from the mechanisms of drug clearance and the extent of binding to plasma proteins and to tissues (Chap. 9).

Knowledge of the relationship between xenobiotic concentrations and effects, or pharmacodynamics, is also important. Effects depend on local concentrations at the site of action, typically at cell membrane receptors or intracellular locations. Serum or plasma concentrations can be correlated with effects only when these concentrations are in equilibrium with concentrations at the site of action. During the absorption and distribution phases, the concentration ratio will be higher than its equilibrium value, yet often the only xenobiotic concentration measured after an acute overdose is one obtained while absorption and distribution are still ongoing. This effect may explain some observations of apparent poor correlation between measured concentrations and toxic effects.

For xenobiotics that bind significantly to plasma proteins, it is the concentration of xenobiotic that is not bound to proteins (the free-xenobiotic concentration) that is in equilibrium with concentrations at the site of action. For most drugs at therapeutic concentrations, the free-drug concentration is an approximately constant percentage of the total drug concentration. The total concentration is what is usually measured in the laboratory. Under these conditions, the ratio of

total concentration to active site concentration is approximately constant, and a reasonable correlation between total concentration and effects can be expected.

A major change in the free fraction occurs after treatment of digoxin toxicity with digoxin specific antibody fragments when the free digoxin concentration falls from approximately 75% of the total concentration to less than 1% as a consequence of digoxin binding by the antidigoxin antibody fragments. At the same time, there is extensive redistribution of digoxin from tissues to plasma, leading to substantial increases in total digoxin concentration. This situation may be further complicated by complex digoxin specific antibody fragments interference in many digoxin immunoassays.

Measurement of free-drug concentrations can clarify such situations.¹⁵ Assays for free phenytoin are available in many laboratories. Assays for other free-drug concentrations may require special arrangements. The availability and expected turnaround time can be provided by the laboratory. For example, for patients treated with digoxin specific antibody fragments, newer immunoassays that use antibodies attached to microparticles or glass fibers give results that can be used to set an upper bound on free-digoxin concentrations and thereby verify adequacy of treatment.²³

Toxicology Screening

A test unique to the toxicology laboratory is the toxicology screen, or “tox screen.” Depending on the laboratory, this term may refer to a single testing methodology with the ability to detect multiple xenobiotics, such as GC/MS; it may refer to a panel of individual tests, such as a drug-abuse screen; or it may be a combination of broad-spectrum and individual tests. The widespread use of the term “tox screen” is unfortunate because this inappropriately implies for many physicians the availability of a test that can confirm or exclude poisoning as a diagnosis. Although there are many more toxic xenobiotics in the world than there are named diseases, most serious poisonings involve a relatively limited number of xenobiotics. Comprehensive drug screens can identify many of these agents but may miss recently introduced therapeutic agents or new designer drugs, such as components of “bath salts.” Moreover, comprehensive toxicology screens typically do not detect ionic substances, including bromide, cyanide, lithium, iron, lead, and other heavy metals, and may miss substances that are toxic at extremely low concentrations, such as digoxin and synthetic cannabinoids. Designer drugs are a problem because for any drug, authentic material must be available to establish its behavior in the assay system. By the time a particular drug is added to the system, it has often been largely supplanted in users by something new. It should be apparent that a negative toxicology screen result cannot exclude poisoning. It is equally true that a positive finding does not necessarily confirm a diagnosis of poisoning. For assays that detect only the presence of a xenobiotic, it is not possible to distinguish benign or therapeutic concentrations from toxic ones. Quantitative tests may falsely suggest toxicity when drug concentrations are measured during the drug’s distribution phase, which may extend for several hours with drugs such as digoxin and lithium. Moreover, the phenomenon of tolerance may allow chronic drug users to be relatively unaffected by concentrations that would be quite toxic to a non-using individual. Because comprehensive drug screens may differ widely among institutions and patterns of exposure also show substantial regional variation, there is limited ability to draw meaningful conclusions from any study of the sensitivity and specificity of such screens for detecting or excluding poisoning.

The predictive power of the result of a toxicology screen depends on a number of factors, including the likelihood of poisoning before receiving the test results (the prior probability or the prevalence), the range of xenobiotics effectively detected, and the frequency of false-positive results. It should be noted that false-positive and false-negative results may be either analytical or clinical in origin. A clinical false-positive result occurs when a xenobiotic is detected that is not contributing to the medical problem (eg, a therapeutic amount of APAP). A clinical false-negative result may occur when the wrong test is ordered (eg, a screen for drugs of abuse for a patient with APAP poisoning).

Although only approximately 2% of laboratories offer comprehensive toxicology screening,⁴ most laboratories offer some sort of testing in response to a request for a toxicology screen. This may vary from a panel of immunoassays for drugs of abuse to a comprehensive screening test performed at a reference laboratory. Other laboratories may offer a focused panel of tests rather than a comprehensive screening analysis. Larger laboratories may have several types of “tox screens” available for use in different situations. Among laboratories that do not limit their tests exclusively to commercially available methods, it is likely that no two will have exactly the same menu of drugs that can be reliably detected. Given the trends toward increasing automation and decreasing personnel in clinical laboratories, it is relevant to ask what benefits may be derived from such testing. Studies show that comprehensive toxicologic screening has the potential to provide significant information, with utility varying with the indication for testing. The prevalence of positive results has ranged from 34% to 86% of specimens submitted for testing. When drug exposure, as predicted from the patient’s history and physical examination, was compared with screening results, clinically unsuspected substances were found in 7% to 48% of the cases, and clinically suspected xenobiotics were not found in 9% to 25%.^{13,14,24} However, limited utility is suggested by studies showing that the results of comprehensive screening affect management in fewer than 5% of cases.^{13,14,20,22,28} A survey of emergency physicians found that more than 75% were not fully aware of the range of drugs detected and not detected by their laboratory’s toxicology screen. The majority believed that the screen was more comprehensive than it actually was.¹⁰

One reason for a limited effect on management is the substantial time delay before the results of comprehensive screening are typically available. Generally, more than 3 hours is required for the report of a negative result, and an even

longer time may be required for confirmation of a positive finding. By this time, most consequential management decisions have been implemented. Another possible explanation for the limited utility of screening is that comprehensive screening is largely available only in major medical centers, where consultation from a medical or clinical toxicologist is more likely to be available. Such experts may be more able to make correct diagnoses and initiate appropriate management relying on clinical findings alone.

Several point-of-care devices are capable of rapidly screening urine for the presence of drugs of abuse, as well as TCAs. Results are typically available in 5 to 20 minutes. The accuracy of these devices is typically less than that of laboratory testing.³⁰ In a small study of one such device, diagnosis was believed to have been aided in 82% of cases, and clinical management was changed in 25%.² Additional studies are needed to ascertain the utility of point-of-care drug screening in emergency toxicology.³¹

A useful alternative to the toxicology screen is the toxicology hold. This is a set of serum or urine (or both serum and urine) specimens drawn at the time of presentation, when xenobiotic concentrations are likely to be near maximum concentrations, and initially held refrigerated or frozen without testing. This allows a specimen to remain available for subsequent testing if needed. Most laboratories hold such specimens for several days.

SPECIAL CONSIDERATIONS FOR DRUG ABUSE SCREENING TESTS

Testing for drugs of abuse is a significant component of medical toxicology testing. These tests are widely used in the evaluation of potential poisonings and are assuming an increasing role in assuring the appropriate use of pain medications.⁷ Initial testing is usually done with a screening immunoassay. Although drug-screening immunoassays were initially developed for use in workplace drug-screening programs and are not always optimal for medical purposes, their wide availability, low cost, and ease of use led to their nearly universal adoption in clinical laboratories. Growth of the market for medical drug screening has led to the development of point-of-care tests specifically for medical use, but these devices largely retain the deficiencies of their predecessors. Drug abuse testing for nonmedical reasons is generally considered to be forensic testing, and confirmation of immunoassay results is considered mandatory in such circumstances. Confirmatory testing can compensate for some immunoassay shortcomings but is frequently not done when screening tests are used for medical purposes. Despite the widespread use of drug-screening immunoassays in medical practice, studies suggest that many physicians do not fully understand the capabilities and limitations of these tests.²⁵

The most commonly tested-for drugs are amphetamines, cannabinoids, cocaine, opioids, and PCP. These are often referred to as the NIDA five because they are the five drugs that were recommended in 1988 by the National Institute on Drug Abuse (NIDA) for drug screening of federal employees. (Responsibility for recommendations for federal drug testing now lies with the Substance Abuse and Mental Health Services Administration {SAMHSA}.) Drug-screening immunoassays are also frequently done for methadone and benzodiazepines and less frequently for oxycodone and hydrocodone. Drug-screening devices intended primarily for medical use may also include tests for APAP or TCAs. [Table 6–3](#) lists some of the general characteristics of these tests. Commercial urine immunoassays are also available for buprenorphine, lysergic acid diethylamide, methaqualone, methylenedioxymethamphetamine (MDMA), and oxycodone. Drug-screening immunoassays are available in a number of formats, which may differ in performance. Almost all of them are designed to be used with urine specimens because these can be obtained noninvasively and generally have higher concentrations than serum, enhancing the sensitivity of the test.

TABLE 6–3. Performance Characteristics of Common Drug Abuse Screening Immunoassays^a

Drug/Class	Detection Limits ^a	Confirmation Limits ^a	Detection Interval ^b	Comments
Amphetamines	1000 ng/mL	500 ng/mL amphetamine or MDMA	1–2 days (2–4 days)	Decongestants, ephedrine, L-methamphetamine, selegiline, and bupropion metabolites may give false-positive test results. MDA and MDMA are variably detected. Confirmation of methamphetamine requires detection of >500 ng/mL with >200 ng/mL of metabolite, amphetamine.
Barbiturates	200 ng/mL Secobarbital		2–4 days	Phenobarbital may be detected for up to 4 weeks.
Benzodiazepines	100–300 ng/mL		1–30 days	Benzodiazepines vary in reactivity and potency. Hydrolysis of glucuronides increases sensitivity. False-positive test results may be seen with oxaprozin.
Cannabinoids	50 ng/mL; 20 ng/mL; 25 ng/mL; 100 ng/mL THCA	15 ng/mL THCA	1–3 days (>1 month)	Screening assays detect inactive and active cannabinoids; confirmatory assay detects inactive metabolite THCA. Duration of positivity is highly dependent on screening assay detection limits.
Cocaine	300 ng/mL BE	150 ng/mL BE	2 days (1 wk)	Screening and confirmatory assays detect inactive metabolite BE. False-positive test results due to cross-reactive compounds are unlikely.
Opiates	2000 ng/mL; 300 ng/mL	2000 ng/mL; morphine or codeine	1–2 days; 2–4 days (<1 week)	>10 ng/mL of heroin metabolite 6-monacetyl morphine is also confirmatory. Semisynthetic opioids derived from morphine show variable cross-reactivity. Fully synthetic opioids (eg, fentanyl, meperidine, methadone, propoxyphene, tramadol) have minimal cross-reactivity. Quinolones may cross-react.
Methadone	300 ng/mL		1–4 days	Doxylamine may cross-react.
Phencyclidine	25 ng/mL	25 ng/mL	4–7 days (>1 month)	Dextromethorphan, diphenhydramine, ketamine, and venlafaxine may cross-react.
Propoxyphene	300 ng/mL		3–10 days	Duration of positivity depends on cross-reactivity of metabolite norpropoxyphene.

^aPerformance characteristics vary with manufacturer and may change over time. For the most accurate information, consult the package insert of the current lot or contact the manufacturer. ^bSubstance Abuse and Mental Health Services Administration recommendations¹ are shown as the first value for amphetamines, cannabinoids, cocaine, opiates, and phencyclidine immunoassays and as only values for confirmatory assays. Other commercial immunoassay cutoffs are also listed. Other gas spectrometry cutoffs are set by the laboratory. ^cValues are after typical use; values in parentheses are after heavy or prolonged use.

BE = benzoylecgonine; MDA = methylmethoxyamphetamine; MDMA = methylenedioxyamphetamine; THCA = tetrahydrocannabinolic acid.

The drug-screening tests for cannabinoids and cocaine are directed toward drug metabolites rather than the parent compound. The parent drugs, cocaine and THC, are both short lived and persist for no more than a few hours after use. The metabolites remain present substantially longer. Detection of the metabolites increases the ability to detect any recent drug use. However, this limits the utility of the assays for determining whether a patient is currently under the influence of the drug. Because the metabolites are rapidly formed, a negative test result generally excludes toxicity, but a positive test result indicates only use in the recent past, not current toxicity.

To increase sensitivity for detection of less recent drug use, substrates other than urine can be used for drug screening, including hair and meconium. The latter is used to document intrauterine drug exposure ([Chap. 31](#)). SAMHSA is planning to develop regulations governing the use of hair, saliva, and sweat specimens for federal workplace testing after their performance characteristics have been adequately studied. This can be expected to increase the availability of clinical testing using these substrates. However, testing performed on hair and sweat is unlikely to offer advantages over testing of serum and urine for the management of toxicologic emergencies.

The stigma attached to a positive test result for an abused drug requires that special care be exercised in performing and reporting the test results. To protect citizens' rights, many states have legislated specific requirements for workplace drug screening. In some states, the requirements apply only to screening in the workplace, exempting testing for medical purposes. Laws in other states might apply to all drug screening. Although they are not always legally required, some workplace drug-screening practices have been widely applied to all drug screening.

The use of specific cutoff concentrations is nearly universal. Test results are considered positive only when the concentration of drugs in the specimen exceeds a predetermined threshold. This threshold should be set sufficiently high that false-positive results as a consequence of analytic variability or cross-reactivity are extremely infrequent. They should also be low enough to give consistent positive results in persons who are regularly using drugs. Cutoff concentrations used

vary with the drug or drug class under investigation. In some drug-screening immunoassays, the laboratory has the option of selecting from several cutoff values.

The use of cutoff values sometimes creates confusion when a patient who is known to have recently used a drug has a negative result reported on a drug screen. In such instances, the drug is usually present but at a concentration below the cutoff value. A quantitative confirmatory test (see below) is usually able to demonstrate the presence of the drug or its metabolites under such circumstances. Another potential problem occurs when a patient's drug-screening test result is positive after previously having become negative. This is usually interpreted as indicating renewed drug use, but it may actually be an artifact. Urine drug concentrations are directly proportional to the serum drug concentrations but inversely proportional to the rate of urine production. The rate of the urine flow may vary up to 100-fold, with a resulting possible 100-fold change in the urine drug concentration. This effect is often exploited by individuals who drink large quantities of water before taking a urine drug test to increase urine flow and decrease urine drug concentrations. In contrast, a decrease in the rate of urine production may result in a positive test result after a negative one despite no new drug exposure. A similar effect may be produced by changes in urine pH. Drugs containing a basic nitrogen may demonstrate ionic trapping, with increasing concentrations as urine pH decreases. Similarly, excretion of an anionic drug (eg, phenobarbital) may increase with increasing urine pH. Another widely used practice is the confirmation of positive screening results using an analytical methodology different from that used in the screen, such as an immunoassay screen followed by mass spectrometry based confirmation. The possibility of simultaneous false-positive results by two distinct methods is quite low. Clinical laboratories may differ in their policies with regard to confirmatory testing. Some may confirm all positive results from screening immunoassays, but others may not provide any confirmatory testing unless it is explicitly requested.

The most common confirmatory method is gas chromatography/mass spectrometry (GC/MS). The high specificity afforded by the combination of the retention time and the mass spectrum makes false-positive results extremely unlikely. GC/MS also has greater sensitivity than the screening immunoassays, minimizing failed confirmations because of a drug concentration below the sensitivity of the confirmatory assay. Some states require GC/MS confirmation for workplace drug screening, and it may be legally required for all drug screening.

Immunoassay results can generally be obtained within one hour. Confirmatory testing usually requires at least several hours. This can create a problem when confirmation of initial immunoassay results is considered mandatory. Most laboratories provide a verbal report of a presumptive positive result to facilitate medical management but may not enter the result into a permanent record, such as the laboratory computer, until after confirmation has been completed.

Confirmatory testing is less critical in an emergency department setting because a positive finding infrequently has consequences that extend beyond the medical management of the patient. An exception may occur when results of testing performed on motor vehicle crash victims can be subsequently subpoenaed as evidence in legal proceedings. Confirmatory testing also becomes more important in drug abuse testing associated with chronic pain management programs, in which unexpected findings (whether positive or negative) may result in termination of care.

One workplace drug-screening practice that is not widely followed in medical toxicology is maintenance of a chain of custody. Employers generally insist on chain of custody for workplace testing because actions taken in response to a positive result may be contested in court. A chain of custody provides results that are readily defended in court. Laboratories providing testing for medical purposes rarely keep a chain of custody because it is quite expensive and does not benefit the patient. Additionally, the medical personnel responsible for obtaining the specimens are rarely trained in collection requirements for a chain of custody.

Another practice common in workplace testing but rare in medical laboratories is testing for specimen validity. It is common for individuals to try to "beat" a workplace drug test through a variety of means, including diluting the specimen (either physiologically by water ingestion or by direct addition of water to the specimen), substituting "clean" urine obtained from another individual, or adding various substances that will either destroy drugs in the specimen or inactivate the enzymes or antibodies used in the screening immunoassays. Such substances include acids, bases, oxidizing agents (bleach, nitrite, peroxide, peroxidase, iodine, chromate), glutaraldehyde, pyridine, niacin, detergents, and soap. SAMHSA requires validity testing for all specimens in federal workplace testing, including measurement of urinary pH, specific gravity, and creatinine concentration, as well as tests for the presence of adulterants.⁸ Dipsticks are available that detect the most common adulterants. However, manipulation or adulteration is rarely a problem in specimens obtained for emergency medical management, and clinical laboratories may not provide validity testing.

A rapidly expanding epidemic of misuse of opioid analgesics and accompanying deaths due to unintentional overdoses has led to the issuance of extensive recommendations, and often regulations, for managing chronic opioid therapy for noncancer pain. The use of periodic urine drug tests to monitor compliance with prescribed medications, as well as to detect use of illicit or unprescribed drugs, is consistently a feature of such recommendations, although there is currently very little evidence that this practice reduces misuse or diversion of prescribed drugs or improves outcomes for patients.⁶ There is evidence that the results of urine drug monitoring are inconsistent with the agreed-upon pain management plan in a very substantial fraction of patients so tested.⁶

The objectives of urine drug testing in chronic pain patients are more complex than either testing during possible toxicologic emergencies or workplace drug testing in that negative results could signal misuse or diversion of a prescribed

opioid, but positive results may indicate illicit drug use. The opioids screening immunoassay is not capable of this task and must be assisted by follow-up testing with a mass spectrometry–based assay capable of distinguishing and quantitating prescription opiates and opioids, as well as key metabolites. This may be done on specimens with a positive screening result to ensure that it is positive for the right reasons and for an unexpected negative result to address the possibility that the expected opioid or its metabolites are actually present but at concentrations too low to give a signal exceeding the cutoff value.

Because of the possible consequences of a positive result in workplace drug testing, all positive results are interpreted by a Medical Review Officer with special training in the pharmacology and metabolism of the tested drugs, as well as the performance characteristics of both the screening and confirmatory tests. No corresponding review is mandated for chronic pain testing, and the interpretation of the results may be left to the patient’s physician, who may not be well prepared for this task.

PERFORMANCE CHARACTERISTICS OF COMMON DRUG-SCREENING ASSAYS

Medical toxicologists, toxicology laboratory directors, and practicing physicians may frequently get questions about the significance of drug-screening assays, particularly about the causes of false-positive results. Often these questions come from an individual who recently had a positive test result. [Table 6–3](#) summarizes drug-screening test performance characteristics, which are discussed in more detail below.

There are problems with all summaries of performance characteristics of urine drug tests. There are multiple manufacturers of urine drug immunoassays. Each uses proprietary antibodies in a proprietary design and thus has unique performance characteristics, including reactivity with target drugs and cross-reactivity with interfering substances. Reviews and summaries often list performance characteristics, especially sources of false-positive results, without identifying the specific manufacturer of the assay. This can lead readers to assume that the interference applies to all immunoassays for the drug in question. Recent summaries that cite interferences described in earlier misleading summaries may further obscure the lack of generality for a reported source of false-positive results. Reformulation of assays can remedy problems that previously existed, but this does not stop older reports of false-positive results that are no longer valid from being recited in current articles. The interference of ibuprofen in a widely used assay for cannabinoids was corrected more than 20 years ago but continues to be cited in contemporary literature.²⁴ Adding further confusion, tabular summaries of interferences may use negative to mean either that the substance does not interfere or that the substance falsely lowers results. The best source of current information is the laboratory that is doing the testing or the manufacturer of a point-of-care device.

Immunoassays for opiates are directed toward morphine but have good cross-reactivity with many (but not all) structurally similar natural and semisynthetic opioids. The extent of cross-reactivity may vary among manufacturers. For example, oxycodone exhibits approximately 30% cross-reactivity relative to morphine in a fluorescence polarization immunoassay but less than 5% cross-reactivity in a number of other screening assays.^{16,27} A failure to appreciate the poor detection of oxycodone can create problems when opiate-screening immunoassays are used to confirm that patients receiving prescription oxycodone for chronic pain are indeed taking it rather than diverting it for illicit sale. If a low cross-reactivity assay is used, a patient taking oxycodone as prescribed might have a negative result, but another patient who is selling the oxycodone and using the proceeds to buy heroin would have a positive result. To address this problem, assays specific for oxycodone have been introduced. These assays are sensitive to therapeutic amounts of oxycodone but relatively insensitive to other opiates.

Synthetic opioids, such as dextromethorphan, fentanyl, meperidine, methadone, propoxyphene, and tramadol, show little or no cross-reactivity in opiate immunoassays. Urine immunoassays specific for meperidine, methadone, and propoxyphene are available. Given the increasing importance of buprenorphine as maintenance therapy for opioid dependency, it is worth noting that the combination of high potency and low cross-reactivity means that buprenorphine will generally not be detected by opiate immunoassays. Immunoassays for specific detection of buprenorphine have therefore been developed.

A positive immunoassay result may reflect multiple contributions from various opiates and opiate metabolites. Concentrations of morphine glucuronide in the urine may be up to 10-fold higher than the concentrations of unchanged morphine and can contribute substantially to positive results. A positive opiate result after the use of heroin (diacetylmorphine) is primarily a result of the morphine and morphine glucuronide that result from heroin metabolism. Distinguishing heroin from other opioids requires detection of 6-monoacetylmorphine, the heroin-specific metabolite. Small amounts of the metabolite may be detected by GC/MS for up to 24 hours after use. A half-life of 5 minutes means that unchanged heroin can only be found in the urine if sampling is done immediately after use.

The duration of positivity of an opiate immunoassay after last use depends on the identity and amount of the opiate used, the specific immunoassay, the cutoff value, and the pharmacokinetics of the individual. Currently, SAMHSA recommends a cutoff equivalent to 2000 ng/mL of morphine for workplace screening because poppy seeds can rarely produce transient positive results with the previously recommended cutoff of 300 ng/mL. However, most toxicology laboratories continue to

use a 300 ng/mL cutoff.

Drug-screening assays for “cocaine” are actually assays for the cocaine metabolite benzoylecgonine, which is eliminated more slowly than cocaine. This extends the duration of positivity after last use from a few hours to 2 days and sometimes to one week or longer after prolonged heavy use. Because the assay is directed toward a metabolite, positive results do not equate with toxicity but merely indicate recent exposure. The assay is highly specific for benzoylecgonine, and false-positive results due to an interfering substance are extremely uncommon (Chap. 78). Point-of-care devices may yield false-positive results because of device failure or operator error. False-positive results may also occur with misidentified specimens or (rarely) intentional specimen adulteration.

Immunoassays for cannabinoids are also directed toward a metabolite, in this case tetrahydrocannabinolic acid. These immunoassays exhibit cross-reactivity with other cannabinoids but little else. Because cannabinoids are structurally unique and occur only in plants of the genus *Cannabis*, false-positive results are uncommon (Chap. 77). It is unusual, although possible, to become exposed to sufficient “secondhand” or sidestream marijuana smoke to develop a positive urine test result.⁵ Legal hemp products include fiber, oil, and seedcake derived from *Cannabis* varieties with low concentrations of cannabinoids. Hemp food products contain insufficient amounts of THC to produce psychoactive effects and usually will not increase urinary cannabinoid concentrations above a 50 ng/mL screening threshold.^{12,25}

Interpretation of a positive result for cannabinoids can be problematic. Urine may be positive for up to 3 days after occasional recreational use. However, with heavy or prolonged use, there may be significant accumulation of cannabinoids in adipose tissue. These stored cannabinoids are slowly released into the bloodstream and can produce positive findings for one month or more. Consequently, little can be concluded from a positive finding in terms of current toxicity. Because positive results in the absence of toxicity are very common and because THC is rarely responsible for serious acute toxicity, NACB guidelines recommend against its routine inclusion in drug screening for patients with acute symptoms.³² Synthetic cannabinoids (found in “spice”) are generally not detected by cannabinoids assays, presumably because of a combination of very low concentrations in urine and limited cross-reactivity.

Amphetamine-screening tests have the greatest problems with false-positive results. A number of structurally related compounds may have significant cross-reactivity, including bupropion metabolites³ and nonprescription decongestants such as pseudoephedrine, as well as L-ephedrine, which is found in a variety of herbal preparations. Some nonprescription nasal inhalers contain L-methamphetamine, the less potent levorotary isomer of D-methamphetamine. It is particularly problematic because it not only cross-reacts in immunoassays but also cannot be distinguished from the D-isomer by mass spectrometry.¹¹ This cross-reactivity is beneficial from the point of view of the medical toxicologist because all of these compounds may produce serious stimulant toxicity. But it is problematic in drug abuse screening because of the widespread legitimate use of cold medications. Assays with greater selectivity for amphetamine or methamphetamine have been developed. Although these assays produce fewer false-positive results caused by decongestant cross-reactivity, they are also less sensitive for the detection of other abused amphetaminelike compounds, including methylenedioxymphetamine (MDA), MDMA, and phentermine. Cross-reactivity patterns vary from assay to assay.¹⁶ The manufacturer’s literature should be consulted for specific details. A number of designer phenethylamine derivatives (such as those found in “bath salts”) might be expected to cross-react in amphetamine assays because of structural similarity. However, they are typically much more potent than amphetamine or methamphetamine and do not achieve high enough concentrations to give a signal exceeding the cutoff.

Testing for benzodiazepines is complicated by the wide array of benzodiazepines that differ substantially in their potency, cross-reactivity, and half-lives. There are also substantial differences in the detection patterns of the various immunoassays.^{12,16} This heterogeneity complicates the interpretation of benzodiazepine-screening assays. Screening results may be positive in persons using low therapeutic doses of diazepam but negative after an overdose of a highly potent benzodiazepine such as clonazepam. To improve the scope of detection, some assays use antibodies to oxazepam, which is a metabolite of a number of different benzodiazepines. These assays may have poor sensitivity to benzodiazepines that are not metabolized to oxazepam. False-negative results may occur for benzodiazepines that are excreted in the urine almost entirely as glucuronides that have poor cross-reactivity with antibodies directed toward an unmodified benzodiazepine. This is one reason for the poor detectability of lorazepam in some screening assays. The latter situation has led to the recommendation that specimens be treated with β -glucuronidase before analysis.¹⁹ Some assays now include β -glucuronidase in the reagent mixture or use antibodies directed toward glucuronidated metabolites. The frequency of false-negative results and the fact that benzodiazepines are relatively benign in overdose have led the NACB guidelines to withhold recommendation for routine screening of urine for benzodiazepines until these problems with the immunoassays are addressed.³²

Barbiturates are comparable to benzodiazepines in their heterogeneity of potency, cross-reactivity, and half-lives, although the differences are less substantial. Specific assays for serum phenobarbital can often help to clarify the significance of a positive barbiturate screen.

Some PCP screening assays may give positive results with dextromethorphan, ketamine, or diphenhydramine but only when these are used in amounts above usual therapeutic quantities. A positive result may serve as a clue to a possible

overdose with any of these substances. Furthermore, much of the illicit PCP actually consists of a mixture of various congeners and byproducts of synthesis. The cross-reactivity of these xenobiotics with the assay varies significantly and may result in false-negative assay results in patients who use PCP.

REGULATORY ISSUES AFFECTING TOXICOLOGY TESTING

Since 1992, medical laboratory testing has been governed by federal regulations (42 CFR part 405 et seq) issued under the authority of the Clinical Laboratory Improvement Amendments of 1988 (often referred to as CLIA-88 or simply CLIA). These regulations apply to all laboratory testing of human specimens for medical purposes regardless of site. They include the universal requirement for possession of an appropriate certificate to perform even the simplest of tests. The remaining requirements depend on the complexity of the test. These regulations become important to the clinician whenever testing is done at the bedside, whether using spot tests or commercial point-of-care devices such as dipsticks, glucose meters, or urine drug-screening devices.

The regulations divide testing into three categories: waived, moderate complexity, and high complexity. Waived tests include a number of specifically designated simple tests, including urine dipsticks, urine pregnancy tests, urine drug-screening immunoassay devices, and blood glucose measurements with a handheld monitor. The only legal requirement for performing waived testing are the possession of an appropriate CLIA certificate (certificate of waiver or higher) and performance of the test in accordance with the manufacturer’s instructions.

There are substantial additional requirements for both moderate and highly complex testing, most of which simply represent good laboratory practice. Table 6–4 lists the most significant of these requirements. Most assays performed with commercial kits or devices are classified as belonging to the moderately complex category. All tests not specifically classified as waived or moderately complex are considered highly complex. This includes essentially all noncommercial tests, including spot tests, because the testing materials have not been subject to review and approval by the Food and Drug Administration.

TABLE 6–4. Major Clinical Laboratory Improvement Amendments (CLIA) Requirements for Laboratory Testing

Waived Tests

- Certificate of waiver
- Follow manufacturer’s instructions exactly

Moderate-Complexity Tests

- CLIA certificate
- Record keeping
- Test method verification
- Written procedures
- Qualified laboratory director
- Personnel educational requirements
- Documented training of all testing personnel
- Annual competency testing of all personnel
- Two levels of controls daily
- Participate in proficiency testing every 4 months
- Verify calibration and reportable range at least every 6 months
- Quality assessment program
- Biennial inspection and certification

High-Complexity Tests

- All moderate-complexity requirements plus
- Qualified onsite supervisor or
- Daily review of all results by qualified supervisor

These regulations have had a substantial impact in all areas of laboratory testing. Some of the most significant effects have been on bedside testing, including spot tests and point-of-care devices. Although clinical laboratories had been following most required practices before the implementation of the regulations, this was usually not the case for testing done at other sites. Most institutions have now established point-of-care testing programs to facilitate compliance with the

regulations, as well as with additional requirements of accrediting agencies, such as The Joint Commission. Any toxicologic or other testing done at the point of care should be set up in consultation with the institutional program. Often, all point-of-care testing is done under a CLIA certificate held by the program. There is frequently a point-of-care testing coordinator who may make recommendations or personally assist in efficiently addressing the assorted requirements.

Table 6–4 lists only the most significant requirements of the regulations implementing CLIA. These regulations continue to evolve. Many states also have laws regulating medical testing. Accrediting agencies such as The Joint Commission may have additional requirements. Consultation with the clinical laboratory or with an institutional point-of-care coordinator is recommended before implementing any testing.

Personnel unaccustomed to quality control and assessment practices may find the CLIA requirements initially burdensome. Nonetheless, compliance is important. Following these practices may lead to a threefold reduction in incorrect results,²⁷ thereby greatly improving the quality of care provided to patients. Moreover, noncompliant testing is illegal under federal law and may also be illegal under state law. Any untoward outcome associated with illegal testing creates a major risk management liability for both the institution and the individual. Additionally, billing for any testing that is not CLIA compliant may be considered fraudulent.

Another area in which the CLIA regulations have impacted toxicology testing is in the provision of infrequently requested tests. Meeting regulatory requirements involves a substantial labor investment even when few patient specimens are being tested. Mounting pressures to reduce laboratory costs make it less likely that laboratories will continue to maintain such assays.

Another important regulation, although not part of CLIA regulations, requires that the medical reason for ordering a test be provided with the order. Federal regulations require that the ordering physician provide the diagnosis that establishes the medical necessity for the test, either by name or by diagnostic code (CPT code). Laboratories may not use a “best guess” to assign codes to undocumented test requests.

SUMMARY

- Although broad spectrum toxicology screens can identify most drugs present in overdosed patients, the results of broad spectrum screens infrequently have altered management outcomes.
- When requesting a screening test, an important and often overlooked item of communication is specifying any xenobiotics of particular concern.
- Xenobiotic concentrations may be useful to make decisions regarding the use of antidotes or if interventions to hasten drug elimination, such as hemodialysis are indicated.
- The predictive power of the result of a toxicology screen depends on a number of factors, including the likelihood of poisoning before receiving the test results (the prior probability or the prevalence), the range of xenobiotics effectively detected, and the frequency of false positive test results.

7 MEDICOLEGAL INTERPRETIVE TOXICOLOGY

Robert A. Middleberg

One of the potential areas of collaboration for toxicologists is the medicolegal setting. This includes working with forensic toxicologists, medical examiners, law enforcement, lawyers, and regulators. In this arena, interpretive toxicology, whether based on analytical findings or theoretical concepts, is routinely used or required to explain issues in criminal and civil proceedings and as the basis for policy making. Often, the concepts associated with forensic interpretive toxicology are presumed to be associated with deceased individuals. In practice, the preponderance of cases involving toxicologic interpretation involves living people and includes specialty testing such as human performance toxicology. Regardless, interpreting the role, or potential role, of xenobiotics in an adverse outcome is typically not straightforward. For example, the use of generally applied pharmacokinetic equations is usually inappropriate, especially in the postmortem setting, yet such is in widespread practice by individuals unfamiliar with the nuances of case-related issues.²⁷ Rarely is any given case accurately interpreted solely based on toxicologic assessment. As such, forensic interpretive toxicology generally involves an integrative approach that draws on an understanding of case history in addition to analytical, toxicologic, pathophysiologic, and specimen-related issues. Individuals called on to interpret the role of xenobiotics in any given case must understand the factors that affect such interpretations and associated limitations. Furthermore, although difficult in many situations, they should attempt to have their opinions firmly supported by science. Other chapters in this text (Chaps. 6 and 34, Special Considerations: SC2 and SC6) cover much of the basic science associated with interpretive issues. This section is meant to focus on specific issues as they relate to medicolegal (forensic) interpretive toxicology.

CASE HISTORY

It has been reported that case history plays a role in interpreting toxicologic findings in about 70% of cases.²⁴ A number of specific aspects of a case history will lead a seasoned toxicologist in a direction that narrows the scientific investigative focus and avoids a shotgun approach to deciphering the role of toxicology in an adverse outcome. Table 7–1 lists some of the more important aspects of the case history that should be considered from the outset to begin the interpretive process. Detailed information about the individual should optimally include anthropomorphic information, vocation, hobbies, medical history, timing of events to the extent possible, and other contextual information.¹⁷ As an example of the importance of this information, consider a case in which an individual suspected of drunk driving worked at a company that manufactured chemicals. One of the chemicals known to be handled by the individual was a substance that coeluted with ethyl alcohol in the gas chromatographic assay used to quantitate the blood alcohol concentration. Without his employment history, the potential for an incorrect interpretation of the data might have occurred.

TABLE 7–1. Important Aspects of Case History Related to Interpretation of Analytical Findings^{17,29}

<i>Aspect</i>	<i>Examples of Information to Be Gathered</i>
Individual history	Age, gender, weight, nationality, habitus, vocation, hobbies, smoking status, drug abuse history
Medical history	Disease processes, known medications, recent treatments or surgeries, resuscitative efforts, history of snoring (important for cases involving opioids)
Recent activity	Last known activity of the individual; description of behaviors; observations of friends, family, acquaintances and coworkers
Timing	When did an event occur? How much time between event and specimen collection? When was the patient last seen?
Cohabitants	Vocations, hobbies, medications
Scene	Description (kempt or unkempt) Search results of cabinets, trash cans, pill vials collected, ambient temperature, odors, plants or fungi, recent Internet searches, unusual books or literature, heating pads or hot water bottles
Position and description of body, if found unresponsive	Clothing, covered or uncovered, body temperature, vomitus
Notes or journals	Indications of intent, mindset

Unfortunately, toxicology is often not initially considered with respect to field investigation of a case. Therefore, important information is often lost, especially in the case of purposeful poisonings. The longer the time between suspicion of a toxicologic aspect to a case and proper investigation, the greater the chance of lost evidence for explaining the situation. The toxicologist can play a key role in mitigating this hindrance. As a significant point of contact with the poisoned or intoxicated individual, the toxicologist has the opportunity to not only ask the individual questions if he or she is conscious but to also ask police, paramedics, and others questions that could assist in not only treatment of the patient, but also address serious questions that often later arise.

Unlike the confidence in the medical diagnosis of poisoning supported by clinical findings or analytical data, it should be recognized that there is rarely surety in the use of toxicologic analysis for medicolegal purposes. Reasonable degree of certainty, the phrase often used as a measure of acceptability in interpretive toxicology, can only be attained through the weaving of multiple pieces of information into a coherent explanation of events.

PREANALYTICAL ISSUES

Ample evidence exists that the major source of error in analytical toxicology is based not on laboratory error, but on preanalytical issues.^{18,39} Preanalytical issues can be defined as those things that can affect an analytical result prior to the specimen(s) arriving at the laboratory. In accordance with ISO (International Organization for Standardization) requirements, mathematical uncertainty should be able to be determined by the analytical testing laboratory.²⁶ It has become an expectation in certain areas of toxicologic testing that such errors be reported for acceptance into legal proceedings.³¹ Although laboratory error can usually be relatively easily quantified, the error associated with issues surrounding samples before arrival at the laboratory is not so easily measured. The myriad of potential preanalytical factors is summarized in Table 7–2.

TABLE 7–2. Preanalytical Factors That Can Affect Interpretation of Findings^{11,61}

<i>Preanalytical Factor</i>	<i>Specific Issue</i>	<i>Potential Effect</i>
Specimen source	Site of collection (eg, collection near site of drug administration)	Falsely elevated results
Specimens	Collection tubes or containers to include preservative or anticoagulants used, storage conditions (temperature, humidity), mislabeling	Inability to detect specific analytes Analyte stability Wrong sample tested Addition of analytes not originally present
Contamination issues	Use of inappropriate collection techniques (eg, ethanol-based swabs, lack of metal-free devices and containers)	Introduction of unintended analytes, potential misassignment of poisoning
Postmortem-specific issues	Specimen collection techniques (eg, anatomical source of blood, nonspecified part of a solid organ, collection of only partial amount of gastric contents)	Falsely elevated or depressed analyte concentrations

Clinical Specimens

With respect to living individuals, where and how specimens are collected from patients, in addition to specimen storage, can adversely affect not only the analytical test but its interpretation as well.⁵¹ For example, although perhaps not protocol, occasionally samples for analysis are collected proximate to the site where they are administered, such as close to an indwelling antecubital fossa catheter. Contamination of such specimens cannot be excluded and can lead to misinterpretation of findings. Although the treatment of patients is the primary concern during medical emergencies, consideration of potential medicolegal issues should be part of the treating professional's assessment, especially in cases involving children, victims of drug-facilitated sexual assault, motor vehicle operation, workplace incidents, suspected poisoning, and other ill-defined situations. Adequate analysis requires that specimen collection be performed appropriately and consideration given to the types of preservatives used in the collection device. Not all collection devices fit the need for all xenobiotics. For example, although fluoride-containing tubes may work well to prevent microorganism-induced ethanol formation, this same preservative may lead to degradation of some organic phosphorus pesticides and make the sample totally useless in cases of suspected fluoride poisoning.^{1,47} In general, it is good practice to collect both preserved and unpreserved blood samples. Serum samples are generally a good choice from living individuals, but this is analyte specific and certainly not preferred for xenobiotics sequestered in red blood cells. Perhaps the most important precaution in this respect is the collection of specimens for legal blood alcohol determination. Not only are tubes containing fluoride (1%–5% w/v) and oxalate (anticoagulant) necessary, but skin cleansing swabs containing ethanol should be avoided.² Specimen storage conditions can significantly adversely affect analyte stability and specimen integrity. Except for specimens such as hair and nail clippings, specimens for toxicologic analysis should not be maintained at room temperature. Minimally, refrigeration is required, but if it is anticipated that a delay between sample collection and testing will occur, then freezing the samples at –20° or –60°C (the choice of temperature being analyte specific) should be considered, making sure to take precautions to prevent tube cracking.¹¹ It is recommended that if a specific xenobiotic or class of xenobiotics is suspected that laboratory personnel should be contacted before specimen collection for guidance on proper collection, preservation, and storage of specimens. Hospitals should have in place a mechanism that ensures retention of specimens beyond the routine time frame for suspect cases. Typically, hospitals maintain specimens from a few days to a few weeks after use compared to up to one year or longer in most forensic cases.^{44,58} In this regard, all available specimens should be maintained. This is especially important in cases in which death is preceded by a relatively long clinical course. Although it cannot be expected that a hospital maintain specimens under a legal chain of custody, maintaining tubes with original identifier labels often suffices for this purpose.¹⁹

Postmortem Specimens

In postmortem situations, the potential for sample contamination is substantial, especially in the face of significant trauma. For example, the spread of gastric or intestinal contents containing xenobiotics of interest can contaminate sources of blood collection and visceral organs.¹⁷ Additionally, other postmortem phenomena can mitigate the potential value of laboratory-based testing (Table 7–3) for interpretation purposes (see the Postmortem Redistribution section later). Specimen

collection should be done by an experienced pathologist who understands the intricacies of site-specific sample collection. Postmortem blood can be obtained from two broadly categorized sources, central (eg, heart) and peripheral sites (eg, femoral and subclavian veins). Not all peripheral sites have the same interpretive value.⁵³ “Blind stick” samples should not be considered appropriate surrogates for proper dissection and visualization of the specimen source.⁴⁰ For example, heart blood should be collected from the right atrium after opening of the pericardial sack, removal of the pericardium, and drying of the heart.^{11,62} Although there is no ideal postmortem specimen, femoral vein blood tends to better reflect circulating concentrations of xenobiotics closer to the time of death, but this is not always the case. It is realized today that even femoral blood may be subject to the same issues as other blood sources (eg, postmortem redistribution {PMR}). Whenever possible, both cardiac and femoral blood should be collected. Because of postmortem changes, heart blood tends to contain higher concentrations of xenobiotics than peripheral blood sites, thus making it a valuable screening specimen but limiting its actual interpretive value. To properly collect femoral vein blood, a dissection and visualization of the femoral vein followed by ligation or clamping of the vessel above the point of collection is recommended to avoid contamination by iliac blood, the latter seemingly representing a cross between peripheral and central blood.¹¹ Visceral organ specimens can be of value in the interpretation of the meaning of blood concentrations in certain situations.^{5,41} Although a plethora of data exist regarding toxicologic findings in blood, there tends to be less data regarding tissues. Nevertheless, certain organs can be of substantial value when considering specific xenobiotics (Table 7–4). Specimen collection tubes and storage conditions, although similar to those described with clinical specimens, tend to be more important with postmortem specimens because of continuous postmortem changes in blood pH, autolysis, and cell lysis, which can affect analyte stability, recovery, and interpretation.⁶¹

TABLE 7–3. Postmortem Phenomena That Can Affect Interpretation of Toxicologic Laboratory Results

<i>Phenomenon</i>	<i>Potential Effect</i>
Analyte stability	Can lead to increased or decreased concentrations of analytes (eg, ethanol and cyanide can both form and degrade in specimens); will affect interpretation of results by assuming too much or too little analyte present
Degree and type of decomposition	Can lead to analytical difficulties in recovery of xenobiotics; bacterial metabolism of xenobiotics can alter preexisting concentrations
Embalming	Can destroy or form xenobiotics or metabolites (eg, cyanide can be destroyed by embalming chemicals; methylation of desmethyl metabolites can occur; can lead to misinterpretation of results)
Entomologic factors	Insect invasion can lead to decreased or altered concentrations of xenobiotics; insects can also be useful to detect xenobiotics in badly decomposed bodies
Plasma vs. postmortem blood distribution differences	Blood and plasma concentrations of xenobiotics may differ widely, so reliance on kinetic data in living persons may not be comparable to postmortem blood findings; postmortem blood is not the same as whole blood in living individuals
Postmortem redistribution or diffusion	Can lead to elevated or decreased concentrations of xenobiotics; misinterpretation of findings
Toxicogenetics	Can lead to unpredictable effects on metabolism; analysis for metabolic status may not be useful because genotype may not equate to phenotype

TABLE 7–4. Potential Value of Postmortem Traditional and Alternative Specimens

Specimen	Value	Issues with Specimen
Bile	Accumulates xenobiotics, eliminated fecally (eg, opiates); therefore, xenobiotics may remain in bile after cleared from blood	Lack of interpretive data; presence of a xenobiotic may not provide temporal information for exposure
Blood	Largest amount of comparative data; easily obtained	Subject to PMR, diffusion, contamination; blind sticks are suboptimal; xenobiotic concentrations can be a combination of acute and chronic exposure, thus hampering interpretation; back calculation to dose ill advised
Brain	For certain xenobiotics, some correlation to effects	Very difficult specimen to handle analytically because of fat content
Gastric contents	Assessment of overdose; investigative purposes in tracking pill source; potential high concentrations of xenobiotics	Time dependent; lack of homogeneity of specimen; can be difficult analytically because of food and other xenobiotics
Hair	Provides exposure history data	Delay between exposure and appearance in hair (~1 week); may prevent acute exposure assessment; external contamination; contamination from sweat and sebum
Kidney	High concentrations of xenobiotics cleared renally allows for ease of detection	Lack of interpretive data; xenobiotics can accumulate because of specific and nonspecific binding, potentially hampering interpretability
Liver	Contains high concentrations of xenobiotics cleared hepatically; can aid in determination of overdose	Xenobiotics accumulate in liver over time, potentially hampering interpretability; can be affected by both PMR and diffusion; xenobiotics not distributed evenly throughout liver
Urine	Xenobiotics (and metabolites) eliminated renally accumulate in urine; may protect xenobiotics from postmortem degradation	Not always present; not always an indicator of acute exposure; analytical issues (deconjugation); no correlation with effects; no back calculation to dose possible
Vitreous humor	Some protection from compositional changes; ethanol determination; postmortem glucose determination	Delay between appearance of xenobiotic in blood versus vitreous

PMR = postmortem redistribution.

Data from Davis GL. Recommendations for the investigation, diagnosis, and certification of deaths related to opioid drugs. *J Med Toxicol* 2012; Oct 17:317-32-76.³

Hair collection should be considered in practically all cases of toxicologic concern, especially in those involving children because this specimen can circumvent arguments of incidental exposure and other issues.⁴⁵ This specimen, after being collected, requires no special storage conditions and can reflect exposure history for the length of hair growth (~1 cm/mo). Controversy regarding external contamination of hair leading to positive findings, although of some concern, does not outweigh the value of this specimen.^{25,33}

Last, iatrogenic toxicologic injury or death, whether unintentional or purposeful, are often not considered or poorly investigated. The involvement of hospital-based risk management often occurs late and valuable evidence that can either incriminate or exculpate individuals gets destroyed before collection and preservation. Protocols in suspicious cases should exist for the area where the individual was located to be considered a “crime scene.” That is, potential useful evidence, including devices and medications, should be gathered and stored.⁵⁵

SPECIAL LABORATORY CONSIDERATIONS

Testing for xenobiotics of interest is varied and inconsistent among laboratories. Hospital-based laboratories tend to be limited in scope compared with toxicology reference laboratories. Even in this latter group, wide variances exist with respect to capability and scope. No interpretation of toxicologic findings should take place without a complete understanding of the testing performed and its limitations in addition to a review of the analytical data by a competent toxicologist. With the development of robust, widely available analytical tools, insufficient testing with respect to medicolegal interpretive matters should no longer occur.

Ideally, all toxicologic analyses are performed under chain of custody, and all findings are confirmed by a separate and distinct analytical test, with at least one, such as mass spectrometry, that provides specific molecular identification.⁴⁶ This process reduces uncertainty in the utility of a finding for interpretive purposes. For example, the use of gas chromatography to identify ethylene glycol in a hospital-based laboratory led to the wrongful conviction and jailing of a mother for poisoning her infant son. The gas chromatographic peak was actually propionic acid. Remarkably, the reporting of ethylene glycol was duplicated by another laboratory. Postconviction analysis determined the misidentification of the peak. In this case, the propionic acid resulted from the inborn error of metabolism disease, methylmalonic acidemia. It has also been determined that 2,3-butanediol also coelutes with ethylene glycol in some gas chromatographic systems.^{15,60}

It is uncommon for hospital-based drug testing to be analytically confirmed. However, a positive screen using an immunoassay is rarely sufficient for medicolegal purposes given the general cross-reactivity of these tests. Most hospital laboratory reports include a disclaimer to this effect. Also, most of this testing is performed using urine, so such screening

tests are neither quantitative nor interpretable with respect to effects on a given individual.

Today, advanced toxicology laboratories use a combination of tools to help identify xenobiotics of toxicological concern. Many of these tests are performed rapidly and, in some sense, inexpensively compared with the offered breadth of testing. Instruments such as liquid chromatography time of flight (LC-TOF) have revolutionized broad-based toxicology testing. This technique allows for the rapid screening of a patient sample in minutes covering hundreds of chemically dissimilar compounds with identification using exact mass.²³ Liquid chromatography/tandem mass spectrometry (LC-MS/MS), although somewhat less amenable to broad-based screening, has a similar utility with an easier approach, in general, to quantitative analysis.⁴² Both devices are appearing in hospital-based laboratories and should help the toxicologist significantly in evaluating potentially poisoned patients.²² Other instruments, such as inductively coupled plasma mass spectrometry and inductively coupled plasma optical emission spectroscopy used for the analysis of the majority of metals, are still generally found in specialty laboratories and most likely will not be cost effective in the hospital laboratory ([Chap. 6](#)). In all cases, however, the toxicologist should understand the limitations of these devices that can lead to false-positive and false-negative findings.

CORRELATING FINDINGS OR THEORY TO CASE-RELATED ISSUES

Ultimately, the toxicologist's role in forensic interpretive toxicology is to correlate analytical findings or theory to an adverse outcome. Although explanations abound, both in concept and practice, plausible explanations are often few. It is rare that findings can simply be taken at face value. For example, it is common for identical findings in two different cases to have two completely distinct interpretations, which should not be surprising or disconcerting. Toxicology has been described as both science and art, with the interpretive aspect based in science, knowledge, and experience.²⁰ Many of the following factors need to be considered in rendering rational opinions.

Analytical Surprises

It is not uncommon for individuals to render toxicologic opinions without careful review of the analytical data that help form the basis of the opinions. Simple acceptance of reported results can be a fundamental flaw in medicolegal interpretations. It is helpful to review all available information that led to a reported result before interpretation. [Table 7–5](#) lists some of the important facets of analytical data review that can lead to incorrectly reported results. Although there is no expectation that the toxicologist be an expert in analytical chemistry, familiarity with the key elements that can lead to false-positive, false-negative, or poorly quantified findings should become part of the review process. Errors ranging from the wrong patient number on the analytical data to poor control and calibration of an analytical run to poorly integrated chromatographic peaks are all examples of errors that can invalidate any given finding.

TABLE 7–5. Important Aspects of Laboratory Data Leading to Reporting of Inaccurate Results

<i>Issue</i>	<i>Examples</i>	<i>Effects</i>
Inappropriate method validation	Unable to define limit of detection, limit of quantitation, analytical bias and precision, specificity, analyte and analytical stability, potential interferences	No confidence in the ability to produce a defensible result
No or poor analytical method	No written method to follow	Irreproducibility of results; lack of consistent direction to analysts
Lack of proper calibration or control	No controls included in analytical run, reporting results outside of the analytical measurement range, calibrators and controls prepared from the same stock solution	Unreliable results
Analytical characteristics	Poor chromatography, lack of proper internal standard, poor mass spectral characteristics, improper integration of peaks, improper baseline acceptance	Unreliable results
Administrative errors	Wrong demographics, case numbers, dates, etc. assigned to the data; improper chain of custody	No confidence that correct patient specimens were tested
Failure to follow standard operating procedures	Specified steps in either administrative or technical standard operating procedures were not followed	Lack of confidence in correct patient specimen tested or in analytical results

Postmortem Redistribution

There are many factors related to postmortem changes that complicate the interpretation of well-performed toxicologic test results.^{16,17,38,61} Many of these factors are discussed in [Chap. 34](#). However, the importance of PMR, a long-established principle in forensic toxicology, cannot be ignored or underestimated. Although recognized in the early 1980s, Prouty and Anderson authored the first codified report of this phenomenon in 1990.⁵⁴ Succinctly, PMR is the term given to changes in site-specific xenobiotic concentrations after death.⁵⁰ These xenobiotic movements postmortem generally result in elevated concentrations in common collection sites such as heart blood. The elevation for some substances can be dramatic, giving the appearance of overdose when no such conclusion is supported by other evidence, including analysis of sites of blood collection where PMR may occur to a lesser degree, such as femoral blood. Although instructed to do otherwise, many pathologists still collect heart blood as a sole source of postmortem blood. In attempting to assist in such situations, investigators often publish ratios of heart blood concentrations to femoral blood concentrations over a series of cases from a given laboratory. The common observation is a widespread range of values often encompassing three- to fivefold or greater differences in magnitude.⁸ The use of such ratios to convert a heart blood concentration to a femoral blood concentration, and by further analogy to a premortem circulating blood concentration, should not be performed. The greatest use of such ratios is to give an idea of the likelihood of PMR for any given xenobiotic based on the mean and range of ratios.⁴³ Because it cannot be predicted if PMR occurred in any given case and if so to what degree and over what time period, such calculations have no basis for antemortem blood concentration determination. Another confounder to the use of ratios is the possibility that site-specific differences are not due to PMR but merely a reflection of incomplete distribution before death.¹⁷ It is unclear how many of the reported ratios of heart blood to femoral blood actually reflect this process as opposed to true PMR. The proposed mechanisms and influencing factors resulting in PMR are varied and are listed in [Table 7–6](#). It is most likely a combination of factors that lead to PMR in any given case. Interestingly, as noted earlier, PMR is also reported to take place in femoral blood; thus, it should not be taken at face value that any postmortem blood concentration accurately reflects that circulating at and around the time of death.

TABLE 7–6. Factors Affecting Postmortem Redistribution^{16,50}

<i>Factor</i>	<i>Issue or Potential Effect</i>
Volume of distribution	Xenobiotics with high volumes of distribution often correlate with a greater degree of PMR; can lead to falsely elevated concentrations in postmortem fluids and tissues
pH of blood	pH of blood changes postmortem becoming more acidic; can alter ionization of xenobiotics and promote or hinder PMR
Drug reservoirs	Organs of high blood content or flow, tissues that specifically or nonspecifically retain analytes (eg, liver, kidney), and holding vessels (eg, GI organs) can facilitate movement to blood vessels and neighboring organs
Resuscitative efforts	Some demonstration that xenobiotics move in vivo as a result of resuscitative efforts
Breakdown of barriers	Cellular structural changes may cause leaking of xenobiotics from one site to another, including from intracellular sequestration sites
Release of xenobiotics from proteins	Will alter the free to bound ratio, potentially leading to an unreliable reliance on free xenobiotic concentrations
Postmortem metabolism	Can lead to decreased or increased concentrations of xenobiotics postmortem

GI = gastrointestinal; PMR = postmortem redistribution.

At one time it was believed that PMR was associated with basic xenobiotics with a large volume of distribution. Seemingly, however, most xenobiotics, including acidic and neutral xenobiotics, undergoes PMR. Furthermore, PMR occurs for xenobiotics with wide-ranging volumes of distribution. Still other xenobiotics that would be predicted to undergo PMR have experimental evidence to the contrary.⁵⁰ Thus, a priori predictions of PMR for any given xenobiotic without experimental evidence should explicitly state the caveats associated with such a conclusion. It must be stated, however, that PMR does not preclude the interpretation of findings for cause of death determination because the findings represent only one piece of data in a potential myriad of other relevant information.

Another similarly related phenomenon is postmortem diffusion of xenobiotics. In this situation, diffusion of xenobiotics from an area of high concentration to that of a lower concentration occurs. This is most noted when the gastric contents contain a substantial amount of a xenobiotic that migrates across the wall of the stomach into neighboring tissues and blood sources, such as abdominal aorta and iliac vessels. Additionally, perimortem aspiration of gastric contents can lead to significant esophageal, tracheal, and lung concentrations of a xenobiotic, further facilitating diffusion processes.^{10,52}

Alternative Matrices

Although most discussions regarding interpretive toxicology tend to focus on blood concentrations of xenobiotics, clearly in both the living and the dead, alternative matrices have become extremely valuable. It should be recognized that there is no perfect specimen to assess exposure or provide analytical findings in support of impairment. In the living, alternative specimens including hair, oral fluid (OF), and breath are useful. Hair gives a longer window of detection than most other easily obtained specimens.⁶² Analytical precautions, such as rinsing procedures, can be used to minimize some concerns with hair testing.⁵⁶ The utility of hair should not be underestimated, and despite some of its limitations, it can represent the best suited specimen in some cases, such as drug-facilitated sexual assault, especially when more than 24 to 48 hours passed before specimen collection from the time of event, thus often limiting the value of urine or blood testing.³⁵ In such cases, waiting 1 to 3 months before collecting hair will capture the potential exposure period in growing hair. It is especially useful in children to demonstrate acute versus chronic exposure to xenobiotics.⁴⁵ Collection of hair should be from the posterior vertex of the head, which can be easily approximated by drawing an imaginary line over the head connecting the tops of both ears and a line from the bridge of the nose to the nape of the neck.^{11,56} Where the two lines meet in the back of the head provides hair that grows most consistently on the head.³⁴ About a pencil thickness worth of hair should be clipped as closely to scalp as possible.¹² The root ends should be identified either by tying with string or wrapping in foil.¹¹ Virtually any other source of hair can be tested as well, such as pubic and axillary hair, although practical reasons and shorter growth rates tend to make such samples less suitable for testing.

Oral fluid (OF) is gaining ground as a viable specimen type to assess exposure and impairment because obtaining it is noninvasive, and it can be collected at the site of an event, thus eliminating time delays.⁴ Such delays can result in

clearance of a xenobiotic from other specimen types before collection. OF is composed of secretions from the parotid, submaxillary, sublingual, and other smaller glands. Numerous specimen collection devices exist today that circumvent the need to expectorate, which is not a desirable means of specimen collection.⁴⁸ For the most part, non-protein-bound parent compounds appear in OF, although there are exceptions (eg, benzoylecgonine).¹³ Factors that affect how much of a xenobiotic gets into OF include pH of the blood and OF, the pKa of the xenobiotic, and the degree of protein binding. In general, basic xenobiotics get into OF easier than acidic xenobiotics.⁶⁵ OF has been used for therapeutic drug monitoring purposes (eg, theophylline and digoxin).⁶ Although some correlations between blood concentrations and a number of xenobiotics have been made, it must be remembered that OF is susceptible to contamination from residual drug in the oral cavity, smoked drugs, and passive exposure.^{4,13} Despite its promise, there is variability in OF concentrations of xenobiotics not only within the same individual but also among individuals based on influencing factors that facilitate or inhibit secretion of a xenobiotic into OF.⁴ Last, based on the relatively small specimen volumes after OF collection, specialized testing, including tandem mass spectrometry, is often needed to detect the concentrations of xenobiotics present.

Breath testing for alcohol is a mature subject matter, yet when it comes to impairment, there is a current trend for states to move back to blood alcohol determinations. Legal arguments have been the force behind some of this movement.⁴⁹ Breath testing for other xenobiotics is still in its fledgling state. Despite this, the future holds promise for the detection of other xenobiotics in breath with the possibility of roadside breath drug-testing devices.³ The major advantage of this specimen is its lack of invasive collection technique and rapid screening capability.

Alternative matrices from decedents are varied and have included virtually all fluids and tissues (Table 7-4). Practically speaking, however, other than providing qualitative information, for most matrices, there is little data to support utility of a measured concentration to either allow for independent interpretation or correlation to blood concentrations. Although numerous studies exist that suggest such correlations, rarely is there consistency between studies. Even so, situational use of alternative matrices is sometimes warranted (eg, the use of fat or brain to detect volatiles). A specific exception is vitreous humor (vitreous), a specimen that is often extremely valuable postmortem. Vitreous electrolyte measurements provide data that cannot be gleaned from virtually any other specimen type (Table 7-7).⁷ For most xenobiotics, vitreous concentrations lag behind blood concentrations by about 1 or 2 hours. Thereafter, some correlations have been made between vitreous concentrations and those in blood, with the greatest example being ethanol, where there is an approximately 1:1 correlation when equilibrium is reached. Vitreous represents a relatively pristine specimen during decomposition, embalming, exsanguinations, severe peritoneal trauma, and other less ideal situations.²¹

TABLE 7-7. Valuable Vitreous Chemistries

Analyte	Reported Value	Reported Reference Range (mmol/L)
Chloride	Dehydration, water intoxication	105–135
Potassium	Postmortem interval	<15
Sodium	Dehydration, water intoxication	135–150
Urea nitrogen	Dehydration, renal-related problems (eg, azotemia)	8–20
Glucose	Hyperglycemia, DKA, hyperosmolar coma	<200
Ketones	Fasting or starvation, DKA, isopropanol exposure	None detected

DKA = diabetic ketoacidosis.

Data from Collins K: Postmortem Vitreous Analyses. Medscape Reference (accessed July 16, 2013, at <http://emedicine.medscape.com/article/1966150-overview>).⁷

Toxicokinetics and Toxicodynamics

The basics of toxicokinetics (TK) and toxicodynamics (TD) are covered in Chap. 9. The large and unpredictable degree of interindividual variability places practical limits on the use of TK and TD in postmortem interpretation. These same variations affect the pharmacologic response in living patients. Multiple elements related to TK and TD affect the ability to render interpretive opinions of xenobiotics related to an adverse outcome (Table 7-8). Many of these issues are covered elsewhere; however, the use of pharmaco- and toxicokinetic equations warrants special attention.

TABLE 7-8. Factors Affecting the Utility of Toxicokinetic and Toxicodynamic Principles in Interpretive Toxicology^{14,16,17,27}

<i>Criterion</i>	<i>Potential Effect</i>
Xenobiotic–xenobiotic interactions	Can lead to increased or decreased concentrations of analytes, resulting in serious adverse effects; interactions can take place via increased or decreased metabolism or via competitive interactions at target sites (eg, receptors); can give the appearance of intentional overdose
Idiosyncratic response	There is little or no means of identifying an idiosyncratic response after the fact; can result in serious adverse effects, including fatalities
Pathology or pregnancy	Disease states can alter the toxicokinetic and toxicodynamic profiles for a given xenobiotic and resultant effects; pharmaco- and toxicokinetics change in pregnant women (eg, clearance)
Route of administration	Affects body burdens and speed of action of xenobiotics
Tolerance	Can lead to an overestimation of effect of a given xenobiotic concentration; there is no <i>a priori</i> means of determining tolerance
Toxicogenomics	Can lead to unpredictable effects on metabolism; analysis for metabolic status may not be useful because genotype may not equate to phenotype
Toxicokinetic variables	Prevents utility of classic pharmaco- or toxicokinetic equations; there is no <i>a priori</i> means of knowing the value for the necessary variables unique to an individual used in equations (eg, clearance)
Trauma or shock	Associated issues, including blood shunting and decreased organ perfusion, can alter toxicokinetic factors

Toxicologic emergencies and overdoses often lead to derangement of normal physiological functions. Distortions, especially in liver and kidney function, can significantly alter normal TK parameters.^{59,63} Coupled with pharmacogenetics, drug–drug or drug–xenobiotic interactions, pathophysiology, and other significant factors, the use of routine TK equations can lead to grossly under- or overestimates of a specific measured value. Nevertheless, in a living patient, TK equations can be useful to estimate certain parameters (eg, dose and, in part, form the basis of such useful tools as nomograms). Postmortem, because of PMR and postmortem diffusion alone, the use of TK formulas to predict premortem concentrations or dosing is not generally an acceptable practice. For example, the use of the following formulas will lead to either an absurd dose calculation or an inappropriate estimate of predicted concentration compared with that reported for compounds undergoing significant PMR:^{14,27}

$$\text{Dose} = \text{Reported concentration} \times \text{Volume of distribution} \times \text{Body mass}$$

$$\text{Concentration} = \frac{\text{Dose}}{\text{Volume of distribution} \times \text{Body mass}}$$

Nevertheless, such calculations, although ill advised, are routinely performed and can provide grossly misleading information. “Back extrapolating” from a postmortem concentration to some concentration earlier in time using half-life is fraught with the same perils in that the beginning assumption of an unchanged postmortem blood concentration can rarely be made.¹⁶ Additionally, it is never known how much of any measured blood concentration resulted from a single or multiple dosing. Despite these issues, the toxicologist may be pressured into providing dosing information or predicting a blood concentration during life. The safest avenue in this respect is not to accede to such pressures because the scientific underpinnings are shaky at best.

Assessing Impairment

There exist two broad areas of concern with respect to impairment, that from alcohol and that from other xenobiotics. Impairment caused by alcohol has been long studied, and general conclusions are usually reached with some confidence. The same cannot be stated for impairment caused by drugs. Ultimately, conclusions of drug impairment are based on physical examination by a trained clinician, dosing information, length of time taking a medication, co-administered medications, pathophysiology, observed behaviors, measured concentrations in blood or serum or plasma, and any other

useful information.³² The use of the term “consistent with” is common in assessing impairment in any given individual and might very well be the best opinion that can be offered. Mitigating factors, including tolerance, single versus multiple dosing, reason for the presence of the substance, timing and route of administration, and pathophysiology, all make firm conclusions difficult, especially when blood findings are the first indication of potential impairment (ie, no visible signs of impairment).^{28,57} Great care must be exercised in evaluating or predicting impairment from drugs given the implications of such conclusions. There is currently no scientific support for back extrapolation of drug concentrations based on blood findings. It cannot be stressed enough that urine findings should never be used to assess impairment because the predictive value is limited.⁶⁴ Similar to blood alcohol concentration, many states and countries have developed per se drug laws that presume guilt by the presence of certain drugs or metabolites over some prescribed reportable concentration, even in urine, thus mitigating the need for interpretation in most cases. For example, the presence of carboxy-tetrahydrocannabinol, an inactive metabolite of marijuana, is used to convict drivers of impaired driving; for clarity, this is a legal issue, not a scientific issue.^{30,36} Last, tables and texts that list xenobiotics and determined concentrations in blood and other specimens should only be used as a guide for interpretive purposes because every case is unique.

SUMMARY

- Toxicologists have the opportunity based on both contact with patients and as consultants to be involved with medicolegal cases.
- To properly assess such cases, a holistic approach should be taken that involves the following integration of detailed historical information: preanalytical issues and understanding of the analytical work performed (including its limitations), specimen-specific utility, and special aspects that can weaken or strengthen the ability to form medically and scientifically sound conclusions.
- It should be understood that the burden on the toxicologist is not generally “absolute certainty” because this is something that is rarely achievable. Reasonable medical or scientific certainty usually carries the day, and in civil cases, a greater than 50% probability is all that is generally required.
- Regardless, the purpose of the conclusions offered should not be lost, that is, to educate someone or a group of individuals who have to make difficult decisions, some of which infringe on civil liberties and freedoms. In that respect, the burden assumed by toxicologists should be recognized as significant and warrant the same attention to detail with medicolegal opinions as treatment and diagnosis of a poisoned patient.

8 TECHNIQUES USED TO PREVENT GASTROINTESTINAL ABSORPTION

Lotte C. G. Hoegberg and Anne-Bolette Gude

Gastrointestinal (GI) decontamination is a highly controversial issue in medical toxicology. It can play an essential role in the initial management of orally poisoned patients and frequently is the only treatment available other than routine supportive care. Unfortunately, as is true in most areas of medical toxicology, rigorous studies that demonstrate the effects of GI decontamination on clinically meaningful endpoints are difficult to find. The heterogeneity of poisoned patients demands that very large randomized studies be performed because patients who present to an emergency department (ED) may have an unreliable history and a low-risk exposure.^{31,156} These factors, as well as other significant sources of bias, are often hidden in inclusion and exclusion criteria of the available studies. Numerous determinants contribute to the difficulties in designing and completing studies that provide sound evidence for or against a particular therapeutic option. Incontrovertible endpoints, such as complication-specific mortality, also demand exceptionally large studies because the overall morbidity and mortality of poisoned patients are quite low.³¹ Whereas other endpoints, such as the length of stay in the hospital or intensive care unit (ICU), change in xenobiotic concentration, the rate of secondary complications, and the need for specific treatments such as expensive antidotes, must be considered, these surrogate markers are not adequately rigorous and are inadequately precise measures of morbidity. In the science of GI decontamination, we are also faced with the dilemma that randomizing half of a group of potentially ill patients to no decontamination is a significant ethical concern—we rarely omit decontamination unless a minimally toxic exposure has occurred or an effective, safe, readily available, and inexpensive antidote exists. Because acetaminophen (APAP) meets many of these parameters, it has been used both as the xenobiotic of choice in volunteer overdose studies^{42,82,94,152,239} and in the evaluation of actually poisoned patients.⁵³ However, despite its widespread use as a model, the applicability of the management approach for APAP poisoning to other ingestions is limited.

As might be suspected, no available study provides adequate guidance for the management of a patient who has definitely ingested an unknown xenobiotic at an unknown time. Fortunately, in most cases, there is some component of the history or clinical presentation, such as vital signs, physical examination, and focused diagnostic studies such as an electrocardiogram and anion gap, that might offer insight into the nature of the ingested xenobiotic ([Chap. 3](#)).

For many, the ongoing controversy or debate on GI decontamination culminated in 1997 with the publication of the position statements on activated charcoal, orogastric lavage, syrup of ipecac-induced emesis, and whole-bowel irrigation (WBI) from the American Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT),^{43,124,208,224,225} and has evolved from very invasive to a less aggressive approach after subsequent revisions.^{44,125,209,226} Contrary to initial expectations of some, these excellent reviews failed to end the debate; they simply highlighted many shortcomings and ambiguities within this field. A 2000 study concluded that despite having the evidence reviewed and consensus recommendations made, poison specialists at North American poison centers still offered a wide variety of recommendations for GI decontamination.¹¹⁷ The study evaluated decontamination options for a theoretical patient with a serious potentially life-threatening overdose of enteric-coated aspirin. The recommendations made were often inconsistent with the published position statements, and in some cases, were frankly dangerous. Even toxicologists who made substantial contributions to the development of these consensus statements disagreed on certain aspects of the treatment, although to a lesser extent. In a similar study, when an interactive questionnaire was sent to 14 European Poison Centers, significant differences in the protocols for the recommended method of GI decontamination, timing, and intervention doses were found.⁸¹ These differences suggest that there is inadequate evidence available to produce a proper evidence-based answer for many of the decisions in question. In most of the clinical studies that provide evidence to form the basis for the consensus statements, either the proportion of patients with life-threatening ingestions is very small, or these specific patients were excluded from the study. Similarly, there are no studies for most drugs with modified release kinetics, for newly marketed drugs, for patients with mixed overdose, extremes of age, or with significant end-organ dysfunction. Thus, the clinician must often make decisions based on a theoretical approach emphasizing an understanding of basic principles rather than evidence with a substantial level of uncertainty.

More recent studies investigating the trends in GI decontamination in both the advice given by poison centers and the clinical setting demonstrate a considerable decline in the use of all methods of decontamination.^{31,44} One study specifically

evaluating orogastric lavage found that during the years 1993 to 1997, an average of 18.7% of all poisoned patients received orogastric lavage compared with an average of 10.3% of poisoned patients during the years 1998 to 2003. The decline in the use of GI decontamination after the publication of the position statements is also probably a result of the epidemiologic shift in the developed world away from overdoses of more lethal substances, such as salicylates, theophylline, barbiturates, and tricyclic antidepressants, toward benzodiazepines, prescription opioids, serotonergic reuptake inhibitors, and APAP with a natural resultant decrease in morbidity and mortality or the availability of an excellent antidote. Although true, for the Western world, studies in developing countries indicate a different pattern of poisonings with patients ingesting xenobiotics such as organic phosphorus compounds and other pesticides and herbicides with a more lethal toxicologic profile.⁶²

This chapter does not discuss details with regard to the evaluation of the amount and type of xenobiotic ingested or other strategies for managing a patient with an unknown overdose; these issues are discussed in [Chap. 4](#). Rather, the focus is on determining which decontamination technique or combination of techniques is preferred after an indication for GI decontamination has been established. The literature published since the previously mentioned position papers and previous edition of this book is emphasized, existing evidence is summarized, and areas necessitating further investigation are identified. Detailed discussions of activated charcoal and WBI can be found in the corresponding Antidotes in Depth sections, Activated Charcoal (A1) and Whole-Bowel Irrigation and Other Intestinal Evacuants (A2). A limited discussion on induced emesis is presented here because it is no longer considered an appropriate intervention. In addition, when the ingested xenobiotic is known, readers should also refer to the decontamination sections found in Chaps. 35 through 128, which will offer insight into xenobiotic-specific issues that may alter decontamination strategies.

GASTRIC EMPTYING

The principal theory governing gastric emptying is very simple: If a portion of xenobiotic with substantial toxic potential can be removed before absorption, this potential toxicity should be either prevented or minimized. From 1982 to 1995, several important clinical trials attempted to define the role of gastric emptying in poisoned patients.^{6,29,48,103,148,177,223} Although all of these studies were flawed because of the inclusion of a large number of low-risk patients, numerous restrictive exclusion criteria, and a variety of other biases, they clearly demonstrated that many patients can be successfully managed without aggressive gastric emptying. From 1995 until the present, few additional studies on gastric emptying have been published, and the series of updated position papers in 2004 and reviews further emphasized the limited need for aggressive gastric emptying in poisoned patients.^{7,125,134,226} The studies showed diverging opinions of gastric emptying and no clear evidence to support its clinical effectiveness.^{27,29,63,84,206,207} The clinical parameters listed in [Table 8–1](#) help to identify individuals for whom gastric emptying is usually not indicated based on a risk-to-benefit analysis. In contrast, for a small subset of patients ([Table 8–1](#)), gastric emptying may still be indicated. A thorough understanding of this risk analysis is essential when deciding whether gastric emptying is appropriate for a patient who has ingested a xenobiotic.

TABLE 8–1. Risk Assessment: When to Consider Gastric Emptying	
Gastric Emptying Is Usually Not Indicated If*	Gastric Emptying May Be Indicated If*
<p>The xenobiotic has limited toxicity at almost any dose.</p> <p>Although the xenobiotic ingested is potentially toxic, the dose ingested is likely less than that expected to produce significant illness.</p> <p>The ingested xenobiotic is well adsorbed by activated charcoal, and the amount ingested is not expected to exceed the adsorptive capacity of activated charcoal.</p> <p>Significant spontaneous emesis has occurred.</p> <p>The patient presents many hours postingestion and has minimal signs or symptoms of poisoning.</p> <p>The ingested xenobiotic has a highly efficient antidote (eg, APAP and <i>N</i>-acetylcysteine).</p>	<p>The ingested xenobiotic is known to produce serious toxicity or the patient has obvious signs or symptoms of life-threatening toxicity and</p> <ul style="list-style-type: none">• There is reason to believe that, given the time of ingestion, a significant amount of the ingested xenobiotic is still present in the stomach or• The ingested xenobiotic is not adsorbed by activated charcoal or activated charcoal is unavailable or• Although the ingested xenobiotic is adsorbed by activated charcoal, the amount ingested exceeds the activated charcoal-to-xenobiotic ratio of 10:1 even when using a dose of activated charcoal that is twice the standard dose recommended and• The patient has not had spontaneous emesis or• No highly effective specific antidote exists or alternative therapies (eg, hemodialysis) pose a significant risk to the patient.
<p>*Patients who fulfill these criteria can be decontaminated safely with activated charcoal alone or may require no decontamination at all. *Patients who fulfill these criteria should be considered candidates for gastric emptying if there are no contraindications. For individuals who meet some of these criteria but who are judged not to be candidates for gastric emptying, single- or multiple-dose activated charcoal or whole-bowel irrigation (or both) should be considered.</p>	

Time is an important consideration because for gastric emptying to be beneficial, a consequential amount of xenobiotic must still be present in the stomach. Demographic studies have found that very few poisoned patients arrive at the ED within 1 to 2 hours after ingestion. In most studies, the average time from ingestion to presentation was approximately 3 to 4 hours, with significant variations.^{118,125,126,211} This delay diminishes the likelihood of recovering a large percentage of the xenobiotic from the stomach unless the patient has ingested a xenobiotic that slows gastric emptying rates. As is discussed in more depth in the section on orogastric lavage later in this chapter, many authors advise against interventions beyond one hour after ingestion. Actual analysis of the data highlights the arbitrary nature of this limitation. One human volunteer study evaluated the pharmacokinetic effects of diphenhydramine and oxycodone in a simulated APAP overdose.⁹⁰ This model is relevant because of the rapid absorption of APAP and the presence of many such combination products in the marketplace.

Whereas diphenhydramine did not delay gastric emptying significantly, oxycodone delayed the time to peak APAP concentration by approximately one hour. Although GI decontamination was not part of the study protocol, it can be inferred that APAP was available for GI decontamination for a longer time than the one-hour guideline suggests. Case reports frequently demonstrate that poisoned patients still have xenobiotics in their stomach (as confirmed by computed tomography or gastroscopy) as residuals or pharmacobezoars, from 5 hours up to several days after ingestion and even on autopsy.^{60,121}

In fact, markedly prolonged gastric emptying half-lives and gastric hypomotility were demonstrated using gastric scintigraphy in a prospective study of 85 poisoned patients.¹ Remarkably, these findings occurred with ingestions such as APAP, which are not typically expected to prolong gastric emptying. Patients who underwent orogastric lavage did not have significantly different gastric emptying half-lives, suggesting that the procedure itself was not the cause of the gastroparesis, and likewise there was no evidence that activated charcoal affected gastric emptying rates. The authors speculated that stress in an overdosed patient might be part of the etiology of the hypomotility observed and that the management of patients should not be based on the assumption that GI motility is normal.

Assessment of whether or not gastric emptying is appropriate for a patient continues with an evaluation for potential contraindications (Table 8–2). Regardless of the severity of the ingestion and other contributing factors, such as time, there must be no contraindication to gastric emptying procedures. Because the demonstrable benefit of emptying after ingestion of an unidentified xenobiotic is marginal at best, even relative contraindications usually dictate that the procedure should not be attempted. However, the clinical benefit could be sizable if the ingested dose places the patient on the steep portion of the dose–response curve (Chap. 9). Under these circumstances, a small reduction in dose might translate into a significant reduction in toxicity.

TABLE 8–2. Orogastric Lavage: Indications and Contraindications

Indications	Contraindications
The patient meets criteria for gastric emptying (Table 8–1).	The patient does not meet criteria for gastric emptying (Table 8–1).
The benefits of gastric emptying outweigh the risks.	The patient has lost or will likely lose his or her airway protective reflexes and has not been intubated. (After the patient has been intubated, orogastric lavage can be performed if otherwise indicated).
	Ingestion of a xenobiotic with a high aspiration potential (eg, a hydrocarbon) in the absence of endotracheal intubation
	Ingestion of an alkaline caustic
	Ingestion of a foreign body (eg, a drug packet)
	The patient is at risk of hemorrhage or gastrointestinal perforation because of underlying pathology, recent surgery, or other medical condition that could be further compromised by the use of orogastric lavage.
	Ingestion of a xenobiotic in a form known to be too large to fit into the lumen of the lavage tube (eg, many modified-release preparations)

Orogastric Lavage

Many authors have adopted the consensus approach that orogastric lavage should not be considered unless a patient has ingested a potentially life-threatening amount of a xenobiotic and the procedure can be undertaken within 60 minutes of ingestion.¹⁸¹ Since the publication of the clinical studies cited in the 9th edition of this book, studies of orogastric lavage have been scarce.^{3,24,39,72,86,91,125,146,156,177,181} The previous studies observed a modest, varied, and unreliable effect of orogastric lavage.^{83,84,129,130,187} Gastric lavage was shown to be effective in the treatment of few specific xenobiotic poisoning (tetramine rodenticides), where fatality rate was lowered in the patient group that received gastric lavage compared to patients not lavaged.²³⁵ Use of combination therapies with administration of activated charcoal before gastric lavage was described by several,^{3,4,11,25,33,69,72,111,114,132,146,172,180,217,227} but the procedure was not more effective than activated charcoal alone^{26,42,129} and sometimes resulted in increased xenobiotic concentration and worsened clinical outcome.¹¹ In some cases, gastric lavage delays activated charcoal administration further, and considerations to eliminate gastric lavage and only administer activated charcoal should be made in order to initiate the fastest decontamination procedure. The trend in using gastric lavage continually declines.¹³¹ The frequency of gastric lavage procedure varies from lowest frequency (percent compared with total decontaminations using activated charcoal, gastric lavage, syrup of ipecac,

and WBI) in North America (5.7%)³¹ and Scandinavia (7.9%–9%; Denmark and Norway),^{137,237} in Mediterranean countries (30%–32%; Spain and Palestine),^{11,132,192} to the highest frequency in Asia and South American countries, India (34%–>50%),^{24,153} Nepal (43%),³³ and Bolivia (96%).⁷⁰ The frequency tends to correlate with the type of xenobiotic ingested, with highest frequency of lavage in regions where insecticides such as organic phosphorus compounds and carbamates are more commonly ingested.^{24,33,70}

It is important to highlight the differences between volunteer studies using therapeutic doses of drugs and actual patients with clinically significant overdoses. The most important aspect of this comparison is a bias against gastric emptying and toward a benefit with activated charcoal. The drugs used in volunteer studies are typically well adsorbed by activated charcoal, and the doses of activated charcoal are significantly in excess of the activated charcoal:drug ratios that can be achieved in clinically significant overdoses. Larger overdoses, as might occur in patients with clinically important ingestions, are likely to saturate activated charcoal. An additional bias is introduced against gastric emptying because the small amounts of any study drug used are unlikely to alter gastric motility, and thus the drugs may pass through the pylorus before orogastric lavage can occur. A synthesis of available data can be used to develop indications for orogastric lavage (Table 8–2). This procedure should always be performed by trained health care professionals and in health care settings. When deciding whether to actually perform orogastric lavage on a poisoned patient, these indications, contraindications, and potential adverse effects must be considered. Table 8–3 summarizes the technique of orogastric lavage.

TABLE 8–3. The Technique of Performing Orogastric Lavage

Select the correct tube size

Adults and adolescents: 36–40 French

Children: 22–28 French

Procedure

1. If there is potential airway compromise, endotracheal intubation should precede orogastric lavage.
2. The patient should be kept in the left lateral decubitus position. Because the pylorus points upward in this orientation, this positioning theoretically helps prevent the xenobiotic from passing through the pylorus during the procedure.
3. Before insertion, the proper length of tubing to be passed should be measured and marked on the tube. The length should allow the most proximal tube opening to be passed beyond the lower esophageal sphincter.
4. After the tube is inserted, it is essential to confirm that the distal end of the tube is in the stomach.
5. Any material present in the stomach should be withdrawn and immediate instillation of activated charcoal should be considered for large ingestions of xenobiotics that are known to be adsorbed by activated charcoal.
6. In adults, 250-mL aliquots of a room temperature saline lavage solution is instilled via a funnel or lavage syringe. In children, aliquots should be 10 to 15 mL/kg to a maximum of 250 mL.
7. Orogastric lavage should continue for at least several liters in an adult and for at least 0.5 to 1.0 L in a child or until no particulate matter returns and the effluent lavage solution is clear.
8. After orogastric lavage, the same tube should be used to instill activated charcoal if indicated.

Reported adverse effects of orogastric lavage include injury to the esophagus^{34,85} and stomach,⁵⁷ as well as significant decreases in serum calcium,⁸⁰ ionized calcium,⁸⁰ and magnesium⁸⁰; severe hyponatremia¹⁴⁹; and leukocytosis.¹¹¹ Hyponatremia resulted from a lavage that was performed using 12 L of hypertonic saline.¹⁴⁹ An observational case series studying 14 consecutive gastric lavages performed in a resource-poor location found three deaths directly related to the procedure, all of which seemed to have resulted from inadequate airway protection.⁶⁴ These cases, as well as other well-known complications such as respiratory events, including need for mechanical ventilation,¹¹² hypoxemia,¹¹² respiratory failure,²³⁴ and higher frequency of aspiration pneumonitis,^{112,224,226,234} demonstrate that orogastric lavage is not risk free and should only be considered based on the rigorous indications for gastric emptying listed in Table 8–1.

Syrup of Ipecac

Syrup of ipecac-induced emesis is no longer a recommended approach for gastric emptying in the treatment of poisoning. Clinical benefit for the use of syrup of ipecac as a gastric emptying technique has never been proven,^{27,86,101,125} and gastric content may be forced beyond the pylorus, increasing the amount of xenobiotic available for absorption.¹⁸⁷ Since the position statement from AAPCC/EAPCCT in 1997,¹²⁴ the frequency of syrup of ipecac use has declined steadily.³¹ Furthermore, as the benefits of activated charcoal are recognized and the time to its administration evaluated, it has become evident that the administration of syrup of ipecac delays the administration of activated charcoal¹²³ and possibly oral antidotes.

PREVENTION OF XENOBIOTIC ABSORPTION

Activated Charcoal

Activated charcoal continues to be recognized as an effective method for reducing the systemic absorption of many xenobiotics.^{2,7,16,20,77,86,110,119,160,166} For certain xenobiotics, it also enhances elimination through interruption of either the enterohepatic or enteroenteric cycle.⁴⁹ Its superb adsorptive properties theoretically make it the single most useful management strategy for diverse patients with acute oral overdoses.^{12-14,26,42,49,50,79,102,173,174} However, as is true for the other methods of GI decontamination, there is a lack of sound evidence of its benefits as defined by clinically meaningful endpoints. This opinion is reflected both in the consensus statements and reviews and in the overall trend toward not performing decontamination as shown in poison center data^{7,31,44,110,147} (Chap. 136). The consensus opinion concluded that a single dose of activated charcoal should not be administered routinely in the management of poisoned patients and, based on volunteer studies, the effectiveness of activated charcoal decreased with time, providing the greatest benefit in severely poisoned patients if dosed within one hour of ingestion. There was no evidence that the administration of a single dose of activated charcoal improved clinical outcome. These opinions are unfortunately biased by the fact that most “routinely” poisoned patients have low-risk exposures and do well with minimal intervention. Additionally, it is generally accepted that unless either airway protective reflexes are intact (and expected to remain so) or the patient’s airway has been protected, the administration of activated charcoal is contraindicated.⁴⁴ Despite little scientific basis or support from clinical trials, less severely poisoned patients might benefit from activated charcoal in terms of reduced need for life support, monitoring, and antidotes.¹¹⁰

Theoretically, the early administration of activated charcoal to patients presenting with a significant oral overdose of a potentially toxic xenobiotic would lower systemic exposure to that xenobiotic and thus be of benefit to the patient. Surprisingly, this intuitive result has been difficult to demonstrate using clinically relevant endpoints in large unselected populations of poisoned patients, again most likely as a result of inclusion of large numbers of minimally exposed low-risk individuals.

A randomized, controlled clinical trial of all orally overdosed patients (n = 327) presenting to the ED of a large hospital in an urban setting during 16 consecutive months found no difference in clinical endpoints such as length of stay or other outcomes between patients treated with a single dose of activated charcoal compared with no decontamination. The study excluded seven severely poisoned patients who all arrived within one hour of ingestion; the majority of the patients in the trial (nearly 60%) arrived within 2 hours postingestion. The most common xenobiotics ingested were APAP, benzodiazepines, and newer antidepressants all of which have low case-fatality rates.⁵⁴

A larger trial (n = 4629) studying self-poisoned patients from a rural and resource-poor location found no difference in mortality rates between those who received no activated charcoal, single-dose activated charcoal, or multiple-dose activated charcoal (MDAC). The patients primarily ingested pesticides and yellow oleander (*Thevetia peruviana*) seeds, both xenobiotics having very different kinetic properties compared to pharmaceuticals. It is important to note that the first 1904 patients in the control group actually received orogastric lavage, as was the case for all patients presenting within 2 hours of ingestion of substantial amounts of pesticides or potentially toxic xenobiotics because of pressure from the national doctors’ union. Although the authors claim that logistic regression analysis found no influence of lavage on their results, the data are not presented.⁶⁵ Furthermore, in an article on compliance related to activated charcoal, nested within this randomized, controlled trial, it is stated that a large number of patients included in the trial had undergone gastric emptying in some form before being transferred from peripheral hospitals.¹⁵⁰ The results of this trial are probably valid for the authors’ particular setting and patient profiles but cannot be generalized to developed nations. In contrast with the lack of effect on clinical endpoints such as death, a pharmacokinetic analysis from another subset of patients (n = 104) from this large trial found a significant increase in plasma clearance of the *Thevetia peruviana* cardenolides in patients administered both single-dose activated charcoal and MDAC. There was no difference between groups in mortality, but given the absolute numbers of two to three deaths per group, this could be related to a lack of power in the study design.¹⁸²

Mechanism. The entire effect of activated charcoal takes place in the GI tract. Oral activated charcoal is not absorbed through the GI wall but passes straight through the gut unchanged. Administration of xenobiotics may happen by a variety of routes, and these xenobiotics enter or are transported into the GI tract by different mechanisms determined by the specific physical-chemical properties of the individual xenobiotic. To be adsorbed to activated charcoal, the xenobiotic must be dissolved in the GI liquid phase and be in physical contact to the activated charcoal. The surface (internal and external) of activated charcoal is manufactured to possess a chemical nature that attracts certain molecules (xenobiotics). The possible sites of adsorption are indicated in Fig. 8–1. Activated charcoal forms an equilibrium between free xenobiotic and xenobiotic that is adsorbed to it through relatively weak intermolecular forces.

FIGURE 8–1. Mechanism of xenobiotic removal by activated charcoal in the luminal space of the gastrointestinal tract. The position of systemic xenobiotic absorption depends on the physical chemical characteristics of the xenobiotic and takes place from stomach, intestine, or both. Xenobiotic reentry into the luminal space can take place by enterohepatic recirculation and enteroenteric recirculation by active secretion and passive diffusion. Excess and continued supply of activated charcoal facilitates adsorption of recycled xenobiotic and favors continued active and passive diffusion of xenobiotic to the luminal space and adsorption of xenobiotic.

Free xenobiotic + Activated charcoal \rightleftharpoons Xenobiotic/Activated charcoal complex

Desorption of the adsorbed xenobiotic may occur, but if sufficient activated charcoal is present (see dosing below), the equilibrium will be shifted toward the xenobiotic–activated charcoal complex. The effect is a low free xenobiotic concentration in the liquid phase and reduced xenobiotic absorption.⁴⁹

Time Factors. The general statement in the literature is that administration of a single dose of activated charcoal should be considered if a patient has ingested a potentially toxic amount of a xenobiotic that is known to be adsorbed to activated charcoal in the previous hour. This position was chosen based primarily on case reports and volunteer studies using nontoxic doses of xenobiotics because it was believed that there were insufficient data to support or exclude the use of single-dose activated charcoal therapy more than one hour beyond ingestion.^{43,44} However, the efficacy of activated charcoal administered more than one hour after xenobiotic ingestion has been evaluated in several studies. These investigations confirm enhanced effect of activated charcoal if dosed as early as possible but also demonstrate a significant effect if dosing is delayed up to 4 hours after the xenobiotic ingestion.^{75,106,109,110,116,152,202} In fact, a few studies suggest efficacy up to 6 hours after ingestion.^{116,236} Furthermore, prolonged gastric emptying time caused by massive xenobiotic ingestion or specific properties of an ingested xenobiotic or bezoar formation possibly increase the time frame when activated charcoal might effectively adsorb the xenobiotic.^{1,121} The studies below emphasize this concept.

In volunteers, the effect of activated charcoal administered 2 and 4 hours after ingestion of acetaminophen demonstrated no significant difference in plasma acetaminophen concentration compared with control participants. In contrast, when

administered one hour after a simulated acetaminophen ingestion, activated charcoal reduced serum acetaminophen concentrations significantly.²³⁹ Likewise, when the effectiveness of activated charcoal administered 1, 2, and 3 hours after xenobiotic ingestion was determined, only the one-hour group had a pharmacokinetic profile that differed from the control group.⁸² Although these data do not support the administration of activated charcoal as a GI strategy more than one hour after an overdose, the applicability of these results to actual overdosed patients has not been adequately evaluated. The method in this volunteer study was an 8-hour fast followed by a small meal 1 hour before the administration of 3 to 4 g of acetaminophen.^{82,239} Considering the rapid absorption of acetaminophen, the small 3- to 4-g doses used, and the absence of food in the stomach, it is highly probable that little or no acetaminophen would be left in the GI tract to be adsorbed by activated charcoal, limiting the potential time to benefit from activated charcoal to approximately one hour.

In contrast, activated charcoal given 3 hours after an overdose was investigated in vivo, again using acetaminophen and a larger-than-standard dose (ie, 75 g) of activated charcoal. The results demonstrated some benefit in administering activated charcoal 3 hours after an overdose because there were significantly lower serum acetaminophen concentrations in the activated charcoal group than in the control group, 23% lower at 4 hours and 62% lower at 7 hours after ingestion.¹⁹¹ In a similar study, activated charcoal was effective in reducing the systemic absorption of acetaminophen when administered both 1 and 2 hours after ingestion, although the effect of the 2-hour intervention was substantially less than at one hour, reemphasizing the importance of early intervention.⁴²

The efficacy of activated charcoal was studied in 53 patients following 63 episodes of citalopram overdose.⁷⁵ When activated charcoal was administered between 0.5 and 4 hours to 17 patients who had ingested potentially toxic doses of citalopram, there was a 72% increase in clearance and a 22% decrease in bioavailability. In most patients, the activated charcoal was dosed more than one hour after ingestion. Only one patient received activated charcoal within one hour, nine patients received activated charcoal within 1 to 2 hours, and seven patients received activated charcoal within 2 to 4 hours.

Despite a delay to activated charcoal of 0.5 to 6.0 hours after a quetiapine overdose, a significant benefit for a single dose of activated charcoal was demonstrated. Activated charcoal decreased the fraction absorbed of quetiapine by 35%. No apparent effect on clearance was demonstrated.¹⁰⁷ In a later study by the same investigators, only early use (<2 hours) of activated charcoal was able to reduce the probability of intubation in quetiapine overdose patients. Activated charcoal administered between 2 and 4 hours did not reduce the probability of intubation. The study included 286 patients overdosed with quetiapine alone or in combination with other drugs. However, only a total of 42 patients (15%) received activated charcoal based on unknown criteria, four patients (1%) received activated charcoal within 1 hour but were excluded from analysis, 19 patients (7%) received activated charcoal within 2 hours, and 36 patients (13%) received activated charcoal within 4 hours from quetiapine ingestion.¹⁰⁹

A meta-analysis was performed to evaluate the effect of activated charcoal on xenobiotic absorption during the first 6 hours after ingestion. Data were obtained from 64 controlled studies in which activated charcoal was compared with placebo up to 6 hours after drug ingestion in volunteers. Additional considerations were given to assess the influence of physical and pharmacologic properties and the activated charcoal-to-drug ratio. The authors concluded that activated charcoal was most effective when administered immediately after xenobiotic ingestion. However, even with a delay of 4 hours after ingestion, 25% of the participants achieved at least a 32% reduction in absorption, especially when activated charcoal was given with large activated charcoal-to-drug ratios.¹¹⁶

Similarly, when aminotransferase elevations (>1000 IU/L) were measured in patients with acetaminophen overdose who presented more than 4 hours after ingestion, patients who received activated charcoal along with N-acetylcysteine (NAC) had less elevation than those who received NAC alone. Although this study was limited by its observational methodology, the findings are both consistent with studies described earlier and are biologically plausible.²⁰²

Efforts to reduce time to activated charcoal administration have been evaluated using pre-arrival communication between a poison center and both emergency medical services and an ED.^{221,222} Both approaches reduced the time from overdose to activated charcoal dosing to less than one hour.

Thus, it should be clear that the use of a one-hour time frame should serve as a guideline rather than an absolute concept. It is only logical that if an intervention is effective at 59 minutes, it will also be beneficial at 61 minutes. Although it is logical that efficacy decreases as time from ingestion increases, in certain cases, some benefit may be derived many hours after ingestion. Because after massive life-threatening ingestions, the absorption of xenobiotics may be prolonged, there is no exact time limit for activated charcoal use.¹⁵⁷ As discussed earlier, good data from patients with actual ingestions demonstrate that a significant amount of xenobiotic can be found in the stomach beyond this arbitrary one-hour time frame. Activated charcoal should therefore be considered to prevent absorption in poisoned patients even when they present late to medical care. Additional benefits on enhanced elimination are discussed below.

Prehospital Use. Adherence to the recommendation that activated charcoal should be administered within one hour of ingestion limits the potential to treat most poisoned patients. A study over a 6-month period identifying 63 patients who had taken potentially serious overdoses demonstrated a median time of arrival to health care of 136 minutes after the overdose. Only 15 patients presented within 1 hour, and only four of 10 patients who qualified actually received activated charcoal within 1 hour. The results demonstrate not only the difficulty in clinically assessing patients before 1 hour but also the

difficulty in adhering to the principle of treating patients with activated charcoal when they arrive within 1 hour unless activated charcoal could be safely administered to appropriate patients in the prehospitalization setting.¹¹⁸

Prehospital use of activated charcoal has not gained wide acceptance because of the concern that it would not be administered properly by the untrained lay public and that many children would refuse to drink the charcoal slurry. In fact, an 18 month consecutive case series demonstrated that activated charcoal can be administered successfully in the home by the lay public. Home use of activated charcoal significantly reduced the time to activated charcoal administration after xenobiotic ingestion from a mean of 73 ± 18.1 minutes for ED treatment to a mean of 38 ± 18.3 minutes for home treatment.²⁰¹ However, many authorities still recommend that activated charcoal should not be standard home treatment, but administration should only be carried out by health professionals.^{10,45,141,144,156,195,196}

A prospective follow-up study from Finland evaluated the adherence to a new protocol of administering activated charcoal in the prehospital setting. The protocol was implemented by either the first-response unit or paramedics. Activated charcoal was indicated in 722 of 2047 patients. Of these patients, 555 actually received activated charcoal at a mean of 88 minutes after ingestion. There were no adverse effects noted, although 72 patients refused to drink the activated charcoal. This study shows that it is feasible to administer activated charcoal in the prehospital setting, but its clinical implications are unknown.⁵

In reality, many factors, such as the presence of food in the stomach, sustained-release formulations, and co-ingestions that delay gastric emptying, can slow the rate of absorption of a xenobiotic. These factors increase the time frame for possible adsorption to activated charcoal. This increased effect of activated charcoal was demonstrated in a randomized, crossover study in which volunteers were administered acetaminophen in either the presence or absence of the anticholinergic drug atropine and subsequently given a single dose of activated charcoal 1 hour later. Activated charcoal was more effective in reducing acetaminophen bioavailability in the presence of atropine.⁸³

Dosing. The optimal dose of oral activated charcoal has never been fully established. Since the beginning of its clinical use as a GI decontaminant, various factors have been recommended for determining the optimal dose of activated charcoal. Two factors commonly discussed are the patient's weight and the quantity of the xenobiotic ingested. The problem in using the quantity of the xenobiotic as a basis for activated charcoal dosing is that the amount is usually unknown, and there is an implication that nothing else in the GI tract will occupy binding sites on activated charcoal. Additionally, the xenobiotic is often unknown, and xenobiotics vary enormously in their toxicities, rate of absorption, and the clinical effects they produce (eg, respiratory depression, convulsions, and effect on gastric emptying rate). Some xenobiotics are well adsorbed to activated charcoal, but others are not.⁴⁹ Because of variables such as the physical properties of the formulation ingested (liquid, solid, or sustained-release tablet), the volume and pH of gastric and intestinal fluids, and the presence of other xenobiotics adsorbed by activated charcoal,^{14,18,92,95,133,162,164} the optimal dose cannot be known with certainty in any given patient.

Information concerning the maximum adsorptive capacity of activated charcoal for the particular xenobiotic ingested permits a theoretical calculation of an adequate dose,^{8,12,17,19,40,50,158,159,162,163,183,184,186,199,214,219} assuming that the amount of xenobiotic ingested is known. However, clinicians must remain cognizant of the risk of approaching or exceeding the adsorptive capacity of the standard dose of approximately 1 g/kg of body weight of activated charcoal. This possibility has been investigated in some studies.^{8,19,36,95,104,155,186,231}

Thus, the idea that a fixed activated charcoal-to-xenobiotic ratio is appropriate for all xenobiotics is clearly imperfect. It is possible, however, to develop a logical approach to dosing based on available data. The effect of the activated charcoal:xenobiotic ratio is such that theoretically increasing the ratio enhances the completeness of adsorption corresponding to a higher percentage of adsorption and total amount of adsorbed xenobiotic (Fig. 8–2).¹⁵⁷ This was confirmed by Jürgens et al., demonstrating an increasing effect of activated charcoal with increasing activated charcoal–xenobiotic dose, up to a 40:1 ratio.¹¹⁶ The optimal activated charcoal dose is theoretically the minimum dose that completely adsorbs the ingested xenobiotic and, if relevant, that maximizes enhanced elimination. The results of in vitro studies show that the ideal activated charcoal:xenobiotic ratio varies widely, but a common recommendation is to deliver an activated charcoal:xenobiotic ratio of 10:1, or 50 to 100 g of activated charcoal to adult patients, whichever is greater. From a theoretical perspective, this amount will adsorb 5 to 10 g of a xenobiotic, which should be adequate for most poisonings.^{12,13,44,49,163} In human volunteers, the acetaminophen clearance was increased with increasing doses of activated charcoal.⁸⁷ Fixed doses of 50, 25, or 5 g activated charcoal were administered 1 hour after 50 mg/kg of acetaminophen was given. The apparent half-life of acetaminophen was significantly reduced from 2.5 hours for the 5 g activated charcoal dose to 1.9 hours and 1.6 hours for the 25 and 50 g doses, respectively.⁸⁷ The effect of larger doses of activated charcoal, adsorbing larger amounts of xenobiotics was supported by the meta-analysis mentioned earlier.¹¹⁶ Based on available data from in vivo and in vitro studies, the actual recommended dosing regimen for activated charcoal is 50 to 100 g in adults (1 g/kg of body weight) and 0.5 to 1.0 g/kg of body weight in children.^{44,49} These recommendations are generally based more on activated charcoal tolerance than on efficacy. When calculation of a 10:1 ratio exceeds these recommendations, either gastric emptying or MDAC therapy should be considered.

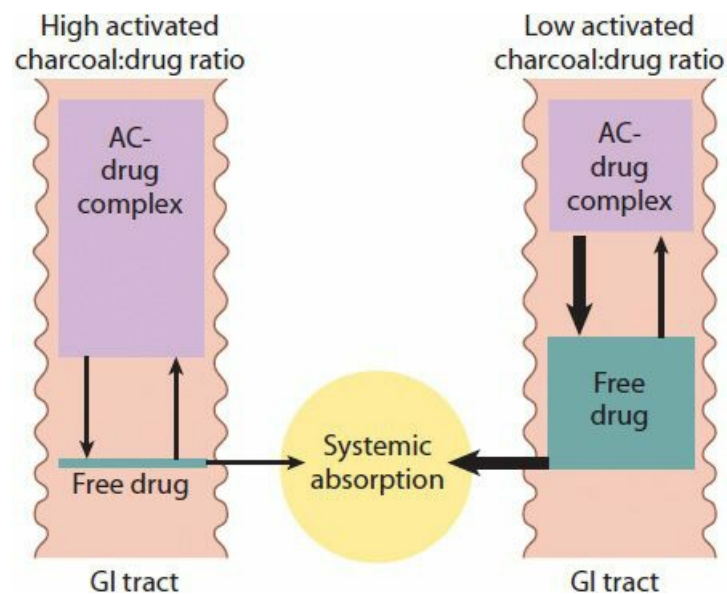

FIGURE 8–2. The effect of high and low ratios of activated charcoal to xenobiotic in the gastrointestinal tract is shown. The reduced systemic absorption achieved when the activated charcoal–xenobiotic ratio is high (left) compared with the increased systemic absorption at a low activated charcoal–xenobiotic ratio (right).

For example, consider a patient who intentionally overdosed by ingesting 30 (0.25-mg) digoxin tablets (total dose, 7.5 mg). Achieving a 10:1 ratio is quite easy, and a standard dose of 1 g/kg might exceed a 10,000:1 ratio. In comparison, consider a patient who intentionally ingests 30 (325-mg) aspirin tablets (total dose, 9.75 g). In this case, obtaining a 10:1 activated charcoal:xenobiotic ratio is quite difficult and is even less likely if a patient ingests 60 or 100 of the aspirin tablets. Poisoning with a combination of xenobiotics may also approach or exceed the maximum adsorptive capacity for the standard dose of activated charcoal, and increasing the dose to reach a higher activated charcoal:xenobiotic ratio might be necessary to consider in multiple-xenobiotic poisonings.⁹⁵

Methods to Increase the Palatability of Activated Charcoal. Activated charcoal has a pronounced gritty texture, and it immediately sticks in the throat because it adheres to the mucosal surfaces and begins to cake.⁴⁹ In addition, the black appearance and insipid taste of activated charcoal make it less attractive.

There have been numerous attempts at making activated charcoal more appealing by providing flavors, including jam,⁵⁸ chocolate syrup,^{142,154} cherry extract or syrup,^{88,168,238} cookie,¹²² juice,¹⁶⁸ sorbitol,^{51,55,143} saccharin,⁵² strawberry flavor,¹⁶⁷ orange or peppermint oil,⁴⁹ melted milk chocolate,^{66,67} chocolate milk,^{39,88,168} soda,^{39,88,168,179} yogurt,⁹⁴ and ice cream.^{40,93,210} The general recommendation, however, remains that activated charcoal should be mixed with water.^{10,115} Because activated charcoal adsorbs the flavoring agents, the palatable taste from added flavors often disappears within minutes after mixing.^{49,51,52,58} However, in cases in which the activated charcoal does not completely adsorb the flavoring agents, they provided a pleasant taste without significantly reducing the adsorptive properties of the activated charcoal.^{49,51,52,93,94}

Effect on Oral Therapeutics. The nonspecific nature and high adsorptive capacity of activated charcoal raises concerns about the simultaneous use of orally administered therapeutics. It would be expected that therapeutics administered shortly before or simultaneously with activated charcoal would be extensively adsorbed, greatly reducing therapeutic efficacy. Restored utility of a therapeutic would be as complex and would depend on all of the factors that influence the efficacy of activated charcoal. Although there is some concern over activated charcoal limiting the efficacy of common oral antidotes such as NAC and succimer, additional concerns arise regarding the administration of oral maintenance medications. For example, activated charcoal might alter the kinetics of the new oral anticoagulants (dabigatran, apixaban, and rivaroxaban).¹⁹⁷ The issue is described to a limited extent and not in the context of poisoning.^{178,203}

Contraindications and Complications. Few clinically significant adverse effects are associated with the use of activated charcoal for poisoned patients.^{49,178} Adverse GI effects are most commonly described, but the frequency varies,¹⁷⁸ and it might be difficult to differentiate from adverse effects resulting from the ingested xenobiotic.¹⁹⁰ In a study of 24 volunteers, mild adverse effects such as abdominal fullness or constipation (46%) and nausea (17%) were most common.¹⁹⁰ In a randomized clinical trial, vomiting was not more frequent in patients treated with activated charcoal compared with the control group, which received no activated charcoal.⁵⁴ Similarly, although vomiting was observed in 22% of patients in a randomized controlled trial of 1103 patients with intentional poisoning, a nonsignificant difference in incidence was reported between patients who had or had not received GI emptying procedures.¹⁵⁰ A prospective cohort study estimating the incidence of vomiting subsequent to the therapeutic administration of activated charcoal to poisoned children younger than 18 years of age showed that one of five of these children vomited. Children with previous vomiting or nasogastric tube administration were at highest risk.¹⁶⁹ This incidence of vomiting appears to be greater when activated charcoal is

administered with sorbitol²²⁵ and after rapid ingestion of larger doses.¹⁵⁷

Pulmonary aspiration of gastric contents containing activated charcoal and inadvertent direct instillation of activated charcoal into the lungs from a misplaced nasogastric tube are rare but severe incidents^{54,74,198} that might lead to airway obstruction, bronchospasm, hypoxemia, aspiration, permanent lung injury, and even death.^{161,166} Administration of activated charcoal to already intubated patients is associated with a low incidence of aspiration pneumonia.¹⁵¹ In fact, pulmonary complications associated with activated charcoal aspiration might be primarily related to the aspiration of acidic gastric contents and not directly related to aspiration of activated charcoal.¹⁸⁵ A retrospective study found that only 1.6% of unselected overdose patients aspirated and that administration of activated charcoal was not found to be an associated risk factor.¹⁰⁶ Pulmonary aspiration in overdose patients who have received activated charcoal is more easily documented because activated charcoal is a very identifiable marker.

Although relatively few reports of clinically significant emesis and pulmonary aspiration resulting from the administration of activated charcoal exist, the severity of these complications is clear. Consequently, it is important to evaluate, particularly in patients determined to be at limited risk from their exposures, whether single-dose activated charcoal therapy is likely to be beneficial based on the indications and contraindications listed in Table 8–4. This is especially true in small children, in whom the risks of nasogastric tube use might outweigh the benefits of activated charcoal.

TABLE 8–4. Single-Dose Activated Charcoal Therapy without Gastric Emptying: Indications and Contraindications

<i>Indications</i>	<i>Contraindications</i>
The patient does not meet criteria for gastric emptying (Table 8–1) or gastric emptying is likely to be harmful.	Activated charcoal is known not to adsorb a clinically meaningful amount of the ingested xenobiotic.
The patient has ingested a potentially toxic amount of a xenobiotic that is well adsorbed by activated charcoal.	Airway protective reflexes are absent or expected to be lost, and the patient is not intubated.
The ingestion has occurred within a time frame amenable to adsorption by activated charcoal or clinical factors are present that suggest that not all of the xenobiotic has already been systemically absorbed.	Gastrointestinal perforation is likely as in cases of caustic ingestions.
Patients with potentially life-threatening toxicity regardless of the time since ingestion as long as no absolute contraindications exist.	Therapy may increase the risk and severity of aspiration, such as in the presence of hydrocarbons with a high aspiration potential.
	Endoscopy will be an essential diagnostic modality (caustics).

MULTIPLE-DOSE ACTIVATED CHARCOAL

MDAC is typically defined as at least two sequential doses of activated charcoal.²²⁵ In many cases, the actual number of doses administered is substantially greater. This technique serves two purposes: (1) to prevent ongoing absorption of a xenobiotic that persists in the GI tract (usually in the form of a modified-release preparation) and (2) to enhance elimination in the postabsorptive phase by either disrupting enterohepatic recirculation or enteroenteric recirculation (“gut dialysis”).

The 1999 position statement of the AACT and the EAPCCT concluded that based on clinical studies, MDAC should be considered only if a patient has ingested a potentially life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. Although data have confirmed enhanced elimination of these drugs, no controlled studies have demonstrated clinical benefit after their ingestion. Volunteer studies demonstrate that MDAC increases the elimination of amitriptyline, dextropropoxyphene, digitoxin, digoxin, disopyramide, nadolol, phenylbutazone, phenytoin, piroxicam, and sotalol, but there are insufficient clinical data to support or exclude the use of MDAC in these patients.²²⁵ A possibly beneficial effect of MDAC has recently been shown in poisonings including *Amanita phalloides* and other *Amanita* spp,^{38,79,113,176} amiodarone,²⁰⁵ carbamazepine,²²⁷ dosulepin,¹⁴⁵ duloxetine,⁶⁹ diquat,²¹⁸ lamotrigine,⁶⁹ phenobarbital,⁴⁶ theophylline,³⁷ valproic acid,²²⁹ and verapamil.¹⁹³ Furthermore, MDAC is recommended in severe poisonings, including with colchicine²⁸ and quinine.¹¹¹ Although technically correct, the preceding statements suffer from a lack of high quality evidence. Because the clinical studies used to formulate this opinion all lack sufficient numbers of significantly poisoned patients, they induce a bias against any benefit of MDAC. Additionally, none of the studies included a detailed analysis of sustained- or extended-release formulations, which are widely used today. Finally, it is noteworthy that the definition of

“life threatening” is highly subjective. Endpoints such as decreased morbidity or rigorously determined lengths of stay should be considered essential in any study design. Three studies with these clinical endpoints were previously discussed.⁸⁷ Unfortunately, their results were discordant, highlighting the difficulties within this field of study.^{30,59,65}

Dosing. Various MDAC regimens were evaluated to optimize the efficacy of activated charcoal.^{105,119} Reduced xenobiotic absorption and enhanced elimination were demonstrated compared with either single-dose activated charcoal or control without activated charcoal.¹¹⁹ The effect of MDAC on elimination was studied in volunteers who were dosed with lamotrigine and oxcarbazepine in therapeutic doses.¹¹⁹ The MDAC dose regimen was 25 g activated charcoal at 6, 12, 24, 36, 48, and 72 hours after a 100 mg lamotrigine dose or 20 g activated charcoal at 12, 24, 36, and 48 hours after a 300 mg oxcarbazepine dose. Each regimen was compared to control subjects with no activated charcoal and one single dose of 50 g activated charcoal at 30 minutes after lamotrigine or oxcarbazepine ingestion, respectively. Pharmacokinetic parameters were evaluated from the serum concentrations of lamotrigine and oxcarbazepine (by measuring the active metabolite 10-hydroxy-carbazepine). Both activated charcoal regimens significantly reduced the total systemic xenobiotic load compared with control subjects with reductions of 51% for lamotrigine and 41% for 10-hydroxy-carbazepine. The elimination half-life for both xenobiotics was significantly shortened with MDAC; 11±3.5 hours (MDAC) versus 25±4.3 hours (control) for lamotrigine, and 9.0±1.5 (MDAC) versus 20±12 hours (control) for 10-hydroxy-carbazepine.¹¹⁹

Intravenous administration of a xenobiotic is an ideal method to evaluate the ability of different MDAC dose regimens to enhance elimination of a xenobiotic in the postabsorptive phase. A total dose of 150 g activated charcoal given as a loading dose of 50 g and the remaining 100 g divided in either 12.5 g every hour, 25.0 g every 2 hours, or 50.0 g every 4 hours during a total time of 8 hours was equally effective in reducing the mean area under the concentration versus time curve (AUC) in volunteers receiving 8 mg/kg of aminophylline intravenously over a period of 60 minutes.¹⁰⁵

Contraindications and Complications. Similar to single-dose activated charcoal, MDAC can produce emesis, with subsequent pulmonary aspiration of gastric contents containing activated charcoal. It is intuitive that these risks are greater with MDAC than with single-dose therapy. One retrospective study attempted to determine the frequency of complications associated with the use of MDAC.⁶¹ The authors identified nearly 900 patients who had received MDAC and found that only 0.6% of patients had clinically significant pulmonary aspiration. Although no patients developed GI obstruction, 9% had hypernatremia or hypermagnesemia without any clinical consequences noted. The authors did not specify whether the multiple-dose regimens administered included the use of cathartics, but the profile of the adverse reactions suggests that these electrolyte abnormalities were probably from cathartic use. Despite the obvious limitations, this study demonstrates a reasonably low rate of complications associated with MDAC.

Table 8–5 summarizes the indications and contraindications for MDAC therapy. Because the optimal doses and intervals for MDAC have not been established, recommendations are based more on amounts that can be tolerated than on amounts that might be considered pharmacologically appropriate. Table 8–6 lists typical dosing regimens. Larger doses and shorter intervals should be used for patients with more severe toxicity. It is reasonable to base endpoints either on the patient’s clinical condition or on xenobiotic concentrations when they are easily measured.

TABLE 8–5. Multiple-Dose Activated Charcoal Therapy: Indications and Contraindications	
Indications	Contraindications
Ingestion of a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, salicylates or theophylline	Any contraindication to single-dose activated charcoal
Ingestion of a life-threatening amount of another xenobiotic that undergoes entero-hepatic or enteroenteric recirculation and that is adsorbed to activated charcoal	The presence of an ileus or other causes of diminished peristalsis
Ingestion of a significant amount of any slowly released xenobiotic or of a xenobiotic known to form concretions or bezoars	

TABLE 8–6. Technique of Administering Multiple-Dose Activated Charcoal Therapy

Initial dose orally or via orogastric or nasogastric tube:

Adults and children: 1 g/kg of body weight or a 10:1 ratio of activated charcoal to xenobiotic, whichever is greater. After massive ingestions, 2 g/kg of body weight might be indicated if such a large dose can be easily administered and tolerated.

Repeat doses orally or via orogastric or nasogastric tube:

Adults and children: 0.5 g/kg of body weight every 4–6 hours for 12–24 hours in accordance with the dose and dosage form of xenobiotic ingested (larger doses or shorter dosing intervals may occasionally be indicated).

Procedure:

1. Add eight parts of water to the selected amount of powdered form. All formulations, including prepacked slurries, should be shaken well for at least one minute to form a transiently stable suspension before the patient drinks it or it is instilled via orogastric or nasogastric tube.
2. Activated charcoal can be administered with a cathartic for the first dose only when indicated. Cathartics should never be administered routinely and never be repeated with subsequent doses of activated charcoal.
3. If the patient vomits the dose of activated charcoal, it should be repeated. Smaller, more frequent doses or continuous nasogastric administration may be better tolerated. An antiemetic may be needed.
4. If a nasogastric or orogastric tube is used for MDAC administration, time should be allowed for the last dose to pass through the stomach before the tube is removed. Suctioning the tube itself before removal may prevent subsequent activated charcoal aspiration.

MDAC = multiple-dose activated charcoal.

Further clinical and toxicokinetic studies concerning MDAC are needed to establish an optimal dosing regimen and to confirm an effect on relevant endpoints. From available data discussed earlier, the dosing and most appropriate dosing intervals should be considered in each individual overdose case including compliance and clinical challenges from complications (eg, emesis and vomiting). Readers are referred to *Antidotes in Depth: A1* for a more detailed discussion of single-dose activated charcoal and MDAC therapy.

WHOLE-BOWEL IRRIGATION

Whole-bowel irrigation represents a method of purging the GI tract in an attempt to expeditiously achieve gut clearance and prevent further absorption of xenobiotics. This is achieved through the oral or nasogastric administration of large amounts of an osmotically balanced polyethylene glycol electrolyte lavage solution (PEG-ELS). WBI was subjected to a thorough literature review, which was published as a revised position statement in 2004.²⁰⁸ The position statement was unable to establish a clear set of evidence-based indications for the use of WBI because no clinical outcome studies have ever been performed. When experimental, theoretical, and anecdotal human experience is considered, the use of WBI with PEG-ELS can be supported for patients with potentially toxic ingestions of sustained-release pharmaceuticals and substantial amounts of metals. Other indications include the ingestion of large amounts of a xenobiotic with a slow absorptive phase in which morbidity is expected to be high, the ingested xenobiotic is not adsorbed by activated charcoal, and other methods of GI decontamination are unlikely to be either safe or beneficial.²⁰⁸ The removal of packets of xenobiotics from body packers can be considered a unique indication for WBI.^{22,215}

Whole-bowel irrigation cannot be applied safely if the GI tract is not intact; there is an adynamic or obstructive ileus; in the presence of significant GI hemorrhage; or in patients with inadequate airway protection, uncontrolled vomiting, or consequential hemodynamic instability that compromises GI function or integrity.^{56,208} Compliance may be an issue because 1 to 2 L/h of PEG-ELS is required for rapid cleansing. These large volumes can be facilitated when the solution is administered via a nasogastric tube.¹³⁶ Additionally, in vitro, the combination of WBI and activated charcoal decreases the adsorptive capacity of activated charcoal or increases the desorption of xenobiotic from activated charcoal,^{17,99,139} especially when the WBI solution is premixed with activated charcoal.¹³⁹ Activated charcoal should therefore be administered immediately after the WBI procedure, rather than simultaneously.

Results from volunteer studies often offer extreme variability in results,^{127-129,138} and significant variations are noted when individual subjects are simultaneously given three different sustained release xenobiotics.¹²⁹ In one study, nine volunteers took sustained-release preparations of 200 mg of carbamazepine, 200 mg of theophylline, and 120 mg of verapamil, and 1 hour after ingestion, they were assigned to 25 g of activated charcoal followed by WBI, 1 L/h PEG-ELS, 25 g of activated charcoal, or water (200 mL). When the combination therapy was compared with activated charcoal alone, it was not more efficient at reducing pharmacokinetic parameters such as AUC (0–24 hours) and C_{\max} (maximum concentration) for carbamazepine and theophylline, but for verapamil, the combination therapy was more effective than activated charcoal alone.¹²⁹ WBI could not be demonstrated to significantly reduce the AUC for sustained-release acetaminophen (75 mg/kg) compared with control participants in a volunteer study in which WBI was initiated 30 minutes after drug ingestion.¹³⁸ In this study, a capsule containing radiopaque markers, which was given simultaneously with acetaminophen, reached colon more rapidly and in a “collected cluster” on the day of WBI administration compared with the control when the markers were spread throughout the GI tract.

In both of these studies, therapeutic or nontoxic doses of pharmaceuticals were used as marker xenobiotics. In actual

overdoses, the pharmacokinetic properties of pharmaceuticals and the effects of decontamination may differ substantially. As mentioned earlier, study designs using activated charcoal and small doses of xenobiotics tend to bias the study toward a benefit of activated charcoal. In an overdose scenario, when the adsorptive capacity of activated charcoal may be exceeded, it is intuitive that the benefits of other modalities would be more evident.

Pharmacokinetic and pharmacodynamic evaluation in venlafaxine-overdosed patients showed that compared with activated charcoal alone, combination therapy of WBI and activated charcoal might be more beneficial based on decreased venlafaxine bioavailability (29% reduction), increased venlafaxine clearance (35% increase), and lower venlafaxine peak concentrations¹²⁸ and resulted in a decreased probability of venlafaxine-induced seizures (odds ratio {OR}, 0.25 for the combination therapy vs 0.48 for activated charcoal alone).¹²⁷

A small, retrospective, descriptive case series of 16 body packers treated with WBI supports the safety of WBI for body packers. Although the complication rate was reported as 12.5% (two of 16), these complications were not serious. One case of mild cocaine toxicity resulted from leakage, and one heroin body packer had to undergo surgery because of retained packages. There was no correlation between the dose of PEG-ELS, drug type, or packet quantity and length of hospital stay. Because there was no control group, it is not possible to evaluate whether WBI influenced any clinical outcome.⁷¹ Clearance of cocaine packets was performed using PEG-ELS WBI in 33% of 61 verified body packers judged not to be able to clear the packets from their gut. A dosage regimen of 1.5 L/h PEG-ELS was continued until all packets had passed, and there was no limit on the total volume given.²²

Whole-bowel irrigation has been used to treat overdoses in pregnant women and children. Two such cases involved iron overdoses in women during the second and third trimesters of pregnancy; both women were treated successfully and without complications.^{220,228} Pediatric case reports describe combined WBI with succimer therapy⁴⁷ and eventually colonoscopic removal of ingested lead pellets.^{47,91} Abdominal radiographs showed two small lead pellets, which WBI failed to remove, therefore requiring endoscopic removal.⁴⁷ Seven days of WBI, however, was ineffective in the removal of approximately 800 ingested lead pellets, which necessitated removal by colonoscopy.⁹¹ Several reports support the use of WBI in children, including an intentional ingestion of mercury,¹⁸⁹ two pediatric body packers,²¹⁶ and a 16 month-old boy who had ingested a significant amount of iron.²³² In the latter case, despite WBI, the iron bezoar was not removed, treatment was eventually stopped, and the bezoar was expelled after a normal diet was resumed.²³²

The current evidence for the clinical efficacy of WBI is divergent, depending on the xenobiotic and its formulation. Additional case reports and series demonstrate the overall safety of WBI as well as some beneficial effects on secondary endpoints, but the benefits remain generally theoretical. The evidence for simultaneous administration of activated charcoal with WBI is contradictory. Although there is little doubt that PEG-ELS reduces the adsorptive capacity of activated charcoal in vitro, it is unclear if this effect has any clinical significance.

The indications for WBI with PEG-ELS are patients with potentially toxic ingestions of sustained-release pharmaceuticals, xenobiotic ingestions with slow absorptive phases when morbidity is expected to be high, and foreign body ingestions. The combination of WBI and activated charcoal should be considered when adsorption of the ingested xenobiotic to activated charcoal is expected to be high. Other uses of WBI remain theoretical because the only support for the efficacy comes from surrogate markers and anecdotal experience. Table 8–7 summarizes the indications and contraindications for WBI.

TABLE 8–7. Whole-Bowel Irrigation: Indications and Contraindications

<i>Indications</i>	<i>Contraindications</i>
Potentially toxic ingestions of sustained-release drugs	Airway protective reflexes are absent or expected to become so in a patient who has not been intubated.
Ingestion of a toxic amount of a xenobiotic that is not adsorbed to activated charcoal when other methods of GI decontamination are not possible or not efficacious	GI tract is not intact. There are signs of ileus, obstruction, significant GI hemorrhage, or hemodynamic instability that might compromise GI motility.
Removal of illicit drug packets from body packers	Persistent vomiting Signs of leakage from cocaine packets (indication for surgical removal)

GI = gastrointestinal.

CATHARTICS

At present, there is no indication for the routine use of cathartics as a method of either limiting absorption or enhancing elimination. A single dose can be given as an adjunct to activated charcoal therapy when there are no contraindications and constipation or an increased GI transit time is expected. Multiple-dose cathartics should never be used, and magnesium-containing cathartics should be avoided in patients with kidney disease (Antidotes in Depth: A2).

SURGERY AND ENDOSCOPY

Surgery and endoscopy are occasionally indicated for decontamination of poisoned patients. As might be expected, no controlled studies have been conducted, and potential indications are based largely on case reports and case series. A prospective, uncontrolled series of 50 patients with cocaine packet ingestion was published more than 20 years ago.³⁵ The patients were conservatively managed and only underwent surgery if there were signs of leakage or mechanical bowel obstruction. Bowel obstruction occurred in three patients, who promptly underwent successful emergency laparotomy; another six patients chose elective surgery. The authors concluded that body packers should be treated conservatively and only operated on for xenobiotic leakage or bowel obstruction.³⁵ A similar study performed a 16-year retrospective analysis of all body packers treated in a single center.¹⁹⁴ Of the 2880 body packers who were identified, 63 (2.2%) developed symptoms of severe cocaine toxicity after rupture of a package, 43 of the 63 symptomatic patients (68%) died before surgery could be initiated, and 20 (32%) underwent emergency laparotomy to remove the drug packets and survived. A more recent report described two body packers who successfully underwent surgery to remove drug packets. In one case, the indications were rupture and signs of cocaine toxicity. In the other case, the indication for surgery was bowel obstruction.¹⁶⁵ Because most packages do not spontaneously rupture, mechanical obstruction is probably the most common reason for surgical removal of ingested drug packets.²¹⁵ Leakage from heroin-containing packages can usually be managed by naloxone infusion, but the lack of antidote when cocaine packages rupture necessitates surgery (Special Considerations: SC5).²¹⁵

Over the years, a few case reports have presented mixed results for the endoscopic removal of drug packets or pharmacobezoars from the stomach.^{41,60,200,204,215} At present, this method is not commonly recommended because of concerns about packet rupture. However, under exceptional circumstances, there is certainly a precedent for attempting this procedure in a highly controlled setting such as an ICU or operating room.

In rare cases of massive iron overdoses when emesis, orogastric lavage, and gastroscopy failed or were estimated to result in an insufficient treatment outcome, gastrotomy was performed. The significant clinical improvement and postoperative recovery indicated that surgery in these particular cases was the correct approach.^{73,89,171} In a case of zinc toxicity resulting from massive chronic coin ingestion, laparotomy and gastrotomy proved essential to remove the more than 270 coins ingested¹⁷⁰ (Chap. 103).

OTHER ADJUNCTIVE METHODS USED FOR GASTROINTESTINAL DECONTAMINATION

Other xenobiotics, such as cholecystokinin, have been considered as adjuncts to standard measures for GI decontamination.^{68,97} Pharmaceuticals that either speed up GI passage or slow down gastric emptying have been administered in an attempt to minimize the absorption of a xenobiotic. In all cases, the results have been negligible, and the potential risks of administering additional pharmacologically active xenobiotics to an already poisoned patient seem to outweigh any benefit.^{9,233} Interventions that reduce the absorption of xenobiotics from the GI tract other than activated charcoal have also been studied, including sodium polystyrene sulphonate for lithium^{23,78,138-140,181,213} or thallium overdose.¹⁰⁰ Human studies showed minimal decreased absorption and increased clearance of lithium when sodium polystyrene sulphonate was administered.^{78,181} Likewise, case reports describe the use of the lipid-lowering resins cholestyramine and colestipol to interrupt the enterohepatic circulation of digoxin, digitoxin, and chlordane to increase elimination.^{21,76,120,175} With the increased use of activated charcoal and availability of digoxin-specific Fab fragments, indications for lipid-lowering resins for cardioactive steroid ingestions seem obsolete. Studies on clay products in vitro have demonstrated a lower efficacy compared with activated charcoal and activated charcoal-kaolin products in the adsorption of Nerium oleander toxins.²¹²

GENERAL GUIDANCE

Only a few studies provide guidance based on meaningful clinical endpoints for GI decontamination. Pharmacokinetic and pharmacodynamic parameters were introduced and systematically evaluated in human venlafaxine, citalopram,

escitalopram, and quetiapine overdose cases,^{107-109,127,128} increasingly popular pharmaceuticals known to cause central nervous system and cardiac toxicity. Cohort studies^{107-109,127,128} have recently evaluated the effect of GI decontamination with the aim to predict cardiotoxicity and the effects of the GI decontamination method chosen in real-life situations that are often inconsistent with the recommendations of the position papers.^{43,125,209,225,226} In a cohort of 436 venlafaxine overdose occasions, activated charcoal increased venlafaxine clearance and decreased the probability of seizures.^{127,128} Similarly, 77 escitalopram patient overdoses were used to develop a pharmacokinetic–pharmacodynamic model that predicted the probability of having abnormal QT as a surrogate for torsade de pointes.²³⁰ In this model, activated charcoal decreased the bioavailability by 31% and reduced the relative risk reduction of prolonged QT interval by 35% after the ingestion of 200 mg of escitalopram or more.²³⁰

The trends in GI decontamination have dramatically shifted toward less intervention over the years. In 2011, of the 2,334,004 human exposure reported to the American Association of Poison Control Centers,³¹ it is remarkable that only 64,866 patients were given single-dose activated charcoal, 1904 were given MDAC, 4126 underwent lavage, and 2040 received WBI. Similar trends are reported elsewhere with no apparent worsening of outcome.¹⁵ These trends in practice noted reflect the overall combined philosophy of the position statements, which are applicable to the vast majority of poisoned patients. They highlight the benign nature of many exposures and the benefits of good supportive care in the typical patient in whom the interventions of decontamination represent more risk than benefit. In contrast, the survey mentioned on the first page of this chapter of recommendations for a theoretical patient with a serious enteric-coated aspirin overdose reveals less consensus in that 36 different courses of action were proposed for the same patient—a situation in which nonintervention may have greater risk to the patient than decontamination. Most of the poison centers and toxicologists did, however, recommend at least one dose of activated charcoal.¹¹⁷ This distinction serves as a reminder that the existing studies and consensus statements cannot be applied to all cases and that a lack of data produces significant uncertainty in choices for GI decontamination in either atypical or severely poisoned patients.⁹⁸

It is essential to note that only one study has ever demonstrated a survival advantage for any form of GI decontamination of poisoned patients.⁵⁹ Its unique design, involving a cohort of patients with life-threatening toxicity, forces a reassessment of all previous and subsequent literature and confirms that the principles of decontamination are sound. It also suggests that the failure of most studies to demonstrate a benefit results not from a failure of the techniques used but from applying decontamination techniques to subsets of patients who were likely to have good outcomes regardless of intervention.

SUMMARY

- The approach to GI decontamination needs to be more individualized than previously thought. No decontamination method is completely free of risks. The indications and contraindications for GI decontamination must be well defined for each patient, and the method of choice must depend largely on what was ingested, how much was ingested, who ingested it, and when it was ingested.
- Evidence now points away from the routine GI decontamination of most patients presenting to an ED with an oral pharmaceutical drug overdose.
- A single dose of activated charcoal alone will be sufficient in moderate-risk patients, and only in a small subset of exceptionally high-risk patients will the benefit of orogastric lavage outweigh the risks.
- Orogastric lavage as a single intervention is reserved for cases in which the ingested xenobiotic is not adsorbed by activated charcoal and there is reason to believe that the ingested xenobiotic is both life threatening and still in the stomach.
- MDAC and WBI have narrowly defined indications, which may broaden in the future as more studies focus on subsets of significantly poisoned patients.
- The absolute time frame for when decontamination is indicated depends on many factors, such as the rate of gastric emptying, the rate of xenobiotic absorption, and the possibility of enterohepatic and enteroenteric recirculation. The commonly stated short time frame of up to 1 hour postingestion for intervention is most likely an artificially constructed evidence-free time limitation and the potential benefits associated with GI decontamination after a potentially serious ingestion.

A1 ANTIDOTES IN DEPTH

Activated Charcoal

Silas W. Smith and Mary Ann Howland

INTRODUCTION

Activated charcoal (AC) is an excellent nonspecific adsorbent. Understanding AC's role in poison management is established by the integration of pharmacologic data, controlled volunteer trials, studies in heterogeneous patients with overdose or poisoning, and clinical experience.²⁴ AC should be considered for a poisoned or overdosed patient after a risk-to-benefit assessment of the presumed ingested substance and patient-specific factors and circumstances.¹¹ Benefits include preventing absorption or enterohepatic recirculation of a potentially toxic xenobiotic; risks include vomiting and subsequent aspiration pneumonitis. A detailed discussion of the merits of AC as a decontamination strategy is presented in Chap. 8.

HISTORY

Activated charcoal, a fine, black, odorless powder, has been recognized for more than two centuries as an effective adsorbent of many substances. Organic chemist Scheele's first use of charcoal to absorb gases in 1773 was followed by Lowitz's use of charcoal with colored liquids in 1791.^{6,84} In 1830, the French pharmacist Touery demonstrated AC's powerful adsorbent qualities by ingesting several lethal doses of strychnine mixed with AC in front of colleagues, suffering no ill effects.⁶ An American physician, Holt, first used AC to save a patient from mercury bichloride poisoning in 1834.^{6,84} However, it was not until the 1940s that Andersen began to systematically investigate the adsorbency of AC and unquestionably demonstrate that AC is an excellent, broad-spectrum gastrointestinal (GI) adsorbent.⁶⁻⁸

PHARMACOLOGY

Chemistry and Preparation

Activated charcoal is produced in a two-step process, beginning with the pyrolysis of various carbonaceous materials such as wood, coconut, petroleum, or peat. This processing is followed by treatment at high temperatures (600°–900°C) with a variety of oxidizing (activating) agents such as steam, carbon dioxide, or acids to increase adsorptive capacity through formation of an internal maze of pores.^{26,56,112} Typical AC surface areas average 800 to 1200 m²/g.¹¹⁰

Mechanism of Action

The actual adsorption of a xenobiotic by AC is believed to rely on hydrogen bonding, ion–ion, dipole, and van der Waals forces, suggesting that most xenobiotics are best adsorbed by AC in their dissolved, nonionized form.²⁶

Pharmacokinetics

Activated charcoal is pharmacologically inert and unabsorbed. Its GI transit time is influenced by the type and quantity of an ingested xenobiotic, fasting and hydration status, muscarinic and opioid receptor xenobiotic properties, perfusion, and the use of associated cathartics or evacuants, among other factors. In six volunteers acting as their own controls, AC alone or administered with sodium chloride, sodium sulfate, magnesium sulfate, or a proprietary cathartic “salt” (36.7% anhydrous citric acid, 17.65% magnesium sulfate, and 45.6% sodium bicarbonate), the GI transit times to fecal evacuation were 29.3 ± 1.2 hours, 24.4 ± 1.2 hours, 15.4 ± 3.0 hours, 17.3 ± 1.9 hours, and 17.5 ± 2.3 hours, respectively.¹¹¹ In 59 overdose patients ingesting acetaminophen (APAP), carbamazepine, cyclic antidepressants, opioid–APAP combinations, and phenytoin who were administered 25 to 50 g of AC with 70% sorbitol solution, median half-lives for gastric emptying, small intestinal transit, and orocecal transit were 82 minutes, 180 minutes, and 210 minutes, respectively.² When these patients are compared with historical controls given AC without sorbitol,¹ the gastric emptying times (158 vs. 58 minutes), small intestinal transit times (218 vs. 75 minutes), and orocecal transit times (300 vs. 90 minutes) in carbamazepine

ingestions and small intestinal transit times (180 vs. 135 minutes) and orocecal transit times (240 vs. 180 minutes) in APAP ingestions were significantly reduced. These subgroups helped power a statistically significant decrease in orocecal transit times from 270 to 210 minutes for the entire overdose group when 70% sorbitol was added to AC.

Pharmacodynamics

The adsorption rate to AC depends on external surface area, and the adsorptive capacity depends on the far larger internal surface area.^{26,27,104} The adsorptive capacity may be modified by altering the size of the pores. Current AC products have pore sizes that range from 10 to 1000 angstroms (Å), with most of the internal surface area created by 10- to 20-Å-sized pores.^{26,28} Most xenobiotics are of moderate molecular weight (100–800 Da) and adsorb well to pores in the range of 10 to 20 Å. Mesoporous charcoals with a pore size of 20 to 200 Å have a greater capacity to adsorb larger xenobiotics as well as those in their larger hydrated forms.⁸¹

When the AC surface area is large, the adsorptive capacity is increased, but affinity is decreased because van der Waals forces and hydrophobic forces diminish.¹⁴³ According to the Henderson-Hasselbalch equation, weak bases are best adsorbed at basic pHs, and weak acids are best adsorbed at acidic pHs. For example, cocaine, a weak base, binds to AC with a maximum adsorptive capacity of 273 mg of cocaine per gram of AC at a pH of 7.0; this capacity is reduced to 212 mg of cocaine per gram of AC at a pH of 1.2.⁸⁰ AC binds amitriptyline hydrochloride with adsorption capacities of 120 and 100 mg per gram of AC in simulated gastric and intestinal fluids, respectively.¹⁴² The adsorption to AC of a weakly dissociated metallic salt such as mercuric chloride (HgCl₂) decreases with decreasing pH because the number of complex ions of the type HgCl₃ and HgCl₄ increases, and the number of electroneutral molecules (HgCl₂) is reduced.⁷ Nonpolar, poorly water-soluble organic substances are more likely to be adsorbed from an aqueous solution than polar, water-soluble substances.²⁶ Among the organic molecules, aromatics are better adsorbed than aliphatics; molecules with branched chains are better adsorbed than those with straight chains; and molecules containing nitro groups are better adsorbed than those containing hydroxyl, amino, or sulfonic groups.²⁶

Activated charcoal decreases the systemic absorption of most xenobiotics, including APAP, aspirin, barbiturates, cyclic antidepressants, glutethimide, phenytoin, theophylline, and most inorganic and organic materials.^{41,100,114} Notable xenobiotics not amenable to AC are the alcohols, acids and alkalis, iron, lithium, magnesium, potassium, and sodium salts.⁴⁵ Although AC's binding to cyanide is less than 4%, the toxic dose is small, and 50 g of AC would theoretically be able to bind more than 10 lethal doses of potassium cyanide. AC is capable of rapidly removing volatile anesthetic gases such as isoflurane, sevoflurane, and desflurane from anesthetic breathing circuits, which is potentially important in patients who are susceptible to or develop malignant hyperthermia.¹⁵

Activated charcoal's efficacy is directly related to the quantity administered. The effect of the AC-to-drug ratio on adsorption was demonstrated both in vitro and in vivo with para-aminosalicylate (PAS). In vitro, the fraction of unadsorbed PAS decreased from 55% to 3% as the AC-to-PAS ratio increased from 1:1 to 10:1 at a pH of 1.2.¹⁰⁸ This study provides the best scientific basis for the 10:1 AC-to-drug ratio dose typically recommended. In human volunteers, as the AC-to-PAS ratio increased from 2.5:1 to 50:1, the total 48-hour urinary excretion decreased from 37% to 4%.¹⁰⁸ Presumably this occurred because more of the PAS was adsorbed by AC in the lumen of the GI tract rather than being absorbed systemically. These same studies demonstrate AC saturation at low ratios of AC to drug and argue for a 10:1 ratio of AC to xenobiotic.

In a meta-analysis of 64 controlled volunteer studies, a sigmoid dose–response curve described the percentage reduction in drug exposure provided by AC: reduction of drug exposure (%) = $8.95 + [86.79 / (1 + 10^{(0.9861 - \log AC/drug)})]$.⁶⁴ According to this formula, AC:drug ratios of 1:1, 5:1, 10:1, 20:1, 25:1, and 50:1 would reduce drug exposures by 9.0%, 30.2%, 44.6%, 58.9%, 62.9%, and 73.0%, respectively. In a subsequent study of volunteers ingesting 50 mg/kg of APAP, reducing a 1-hour postingestion 50-g AC dose to 25 or 5 g caused the APAP area under the concentration versus time curve (AUC) to increase by 23.6% and 59.0%, respectively.⁴⁸

In vitro studies demonstrate that adsorption begins within about 1 minute of AC administration but may not achieve equilibrium for 10 to 25 minutes.^{27,100} AC's clinical efficacy is inversely related to the time elapsed after ingestion and depends largely on the rate of absorption of the xenobiotic. According to a meta-analysis of volunteer studies, the median reductions of drug exposure when AC was administered at 0 to 5 minutes, 30 minutes, 60 minutes, 120 minutes, 180 minutes, 240 minutes, and 360 minutes after ingestion were 88.4%, 48.5%, 38.4%, 24.4%, 13.6%, 27.4%, and 11%, respectively.⁶⁴ Early AC administration is more important with rapidly absorbed xenobiotics, in which AC functions to prevent xenobiotic absorption by achieving rapid adsorption in the GI tract. After a xenobiotic is systemically absorbed or parenterally administered, AC may still enhance elimination through a mechanism referred to as GI dialysis.

Desorption (drug dissociation from AC) may occur, especially for weak acids, as the AC–drug complex transits the stomach and intestine and as the pH changes from acidic to basic.^{42,107,139} Whereas strongly ionized and dissociated salts, such as sodium chloride and potassium chloride, are poorly adsorbed, nonionized or weakly dissociated salts, such as

iodine and mercuric chloride, respectively, are adsorbed. Binding of γ -hydroxybutyrate (800 mg) to AC (10 g) decreased from 84.3% to 23.3% when exchanging simulated gastric for intestinal fluid.⁹⁹ Diminished AC adsorptive capacity in the intestinal lumen may also occur because of AC's rapid adsorption of intestinal fatty acids, which cover rapidly the surface of carbon granules.⁸⁴ Desorption may lead to ongoing systemic xenobiotic absorption over days. In this case, the apparent elimination half-life of the xenobiotic increases, but peak concentrations remain unaffected.¹⁰⁵ The clinical effects of desorption can be minimized by providing sufficient AC to overcome the decreased affinity of the xenobiotic secondary to pH change, such as by using multiple-dose AC.^{68,90,103,115,132} Although ethanol and other solvents such as polyethylene glycol (PEG) are minimally adsorbed by AC, they may decrease AC adsorptive capacity for a co-ingested xenobiotic by competing for AC binding.^{12,105,107,109}

Concomitant Administration of Activated Charcoal with Cathartics or Evacuants

Cathartics are often used with AC; however, evidence suggests that AC alone is comparably effective to AC plus a single dose of cathartic (sorbitol or magnesium citrate).^{3,68,85,86,90,98,104,113} If a cathartic is used, it should be used only once. Repeated doses of magnesium-containing cathartics are associated with hypermagnesemia,^{94,134} and repeated doses of any cathartic are associated with dehydration, hypotension, and severe or fatal fluid and electrolyte derangements.⁴⁰ AC with sorbitol is not recommended for children younger than one year of age.¹¹²

Whole-bowel irrigation (WBI) with PEG electrolyte lavage solution may significantly decrease the in vitro and in vivo adsorptive capacity of AC,⁵⁴ depending on the individual xenobiotic and its formulation.^{10,74} The most likely explanation is competition by PEG for the surface of the AC for solute adsorption.

Related Agents

A superactivated charcoal with a surface area approximately double the current AC formulations is demonstrated in both in vitro and in vivo studies to have greater maximum adsorptive capacity.^{27,124} Endogenous enteric uremic toxins such as indoxyl sulfate are adsorbed by porous carbon microsphere compounds (eg, AST-120) to mitigate glomerular hypertrophy, interstitial fibrosis, and progressive chronic kidney disease.¹²⁹

ROLE OF ACTIVATED CHARCOAL IN GASTROINTESTINAL DECONTAMINATION

Single-Dose Activated Charcoal

It is difficult to assess the efficacy of single-dose AC (SDAC) in a large, single-institution, prospective study involving consecutive adults receiving 50 g of AC for self-poisonings. This study which excluded lithium, iron, heavy metals, monoamine oxidase inhibitors, digoxin, formaldehyde, mushrooms, APAP, methanol, or sustained-release products because SDAC was used in all symptomatic patients, who also received some form of GI intervention.⁹² Not surprisingly, a beneficial effect of SDAC on outcome measures could not be demonstrated in asymptomatic patients. Similarly, a study of routine SDAC administration after oral overdose consisting primarily of benzodiazepines, APAP, and selective serotonin reuptake inhibitors could not demonstrate differences in mortality, length of stay, vomiting, or intensive care admissions.²⁹ A prospective trial of 876 patients comparing SDAC alone with SDAC plus gastric emptying was unable to demonstrate a difference in outcomes, with the exception of patients presenting within one hour of ingestion, although this difference was not sustained after being adjusted for severity.¹¹⁸ However, when evaluating SDAC alone, a meta-analysis of 64 controlled volunteer studies found significant reductions in ingested xenobiotic amounts when SDAC was provided in appropriate quantity (eg, 10:1) and within 240 minutes of exposure.⁶⁴

Research subsequent to this meta-analysis has sustained SDAC's primarily pharmacokinetic advantage, although some improvement in clinically important endpoints has been demonstrated. A healthy volunteer study in 12 patients in which SDAC was provided 15 minutes after supratherapeutic APAP ingestions (60 mg/kg) reduced APAP absorption by a mean of 41%.¹⁴⁵ In nine human volunteers ingesting 5 g of APAP and 0.5 mg/kg of oxycodone, 50 g of SDAC at 1, 2, or 3 hours reduced the APAP AUC by 43%, 22%, and 15%, respectively.⁹⁷ Concentrations of lamotrigine (100 mg), oxcarbazepine (600 mg), and oxcarbazepine's active metabolite, 10,11-dihydro-10-hydroxy-carbamazepine in six volunteers were reduced by 42%, 97.2%, and 95.8%, respectively, by 50 g of AC provided 30 minutes after ingestion.⁶⁹

In a pharmacokinetics and pharmacodynamics evaluation of escitalopram overdose patients, SDAC reduced the absorbed fraction by 31% and reduced the risk of QT prolongation by approximately 35% for escitalopram doses above 200 mg.¹⁴⁴ In 319 patients with 436 venlafaxine overdoses, SDAC or SDAC with WBI significantly decreased the odds of seizure to 0.48 and 0.25, respectively, compared with no decontamination.⁷³ In 176 patients presenting with 286 separate quetiapine overdoses, SDAC administration within 2 hours reduced the probability of intubation by 7% for a 2-g ingestion

and by 17% for a 10-g ingestion, although time to extubation was unaffected.⁶²

Multiple-Dose Activated Charcoal

Multiple-dose AC (MDAC) functions to prevent the absorption of xenobiotics that are slowly absorbed from the GI tract and to enhance the elimination of suitable xenobiotics that have already been absorbed. MDAC decreases xenobiotic absorption when large amounts of xenobiotics are ingested and dissolution is delayed (eg, masses, bezoars), when xenobiotic formulations exhibit a delayed or prolonged release phase (eg, enteric coated, extended release), when GI motility is impaired because of co-ingestants, or when reabsorption can be prevented (eg, enterohepatic circulation of active xenobiotic, active metabolites, or conjugated xenobiotic hydrolyzed by gut bacteria to active xenobiotic).

MDAC's ability to enhance elimination after absorption had already occurred was first reported in 1982.¹³ This report concluded that orally administered MDAC enhanced the total body clearance (nonrenal clearance) of six healthy volunteers given 2.85 mg/kg of body weight of intravenous (IV) phenobarbital.¹³ The serum half-life of phenobarbital decreased from 110 ± 8 to 45 ± 6 hours. An editorial suggested that MDAC enhanced the diffusion of phenobarbital from the blood into the GI tract and trapped it there for later fecal excretion. In this manner, AC was said to perform as an "infinite sink," allowing for "gastrointestinal dialysis" to occur.⁷⁶ These findings were confirmed by studies in dogs and rats using IV aminophylline and shown to be independent of theophylline enterohepatic circulation.^{32,72,88} Subsequent studies using MDAC with IV aminophylline further extended these results to humans.⁵⁹ Using an isolated perfused rat small intestine, the concept of GI dialysis⁸⁸ was elegantly demonstrated because AC dramatically affected the pharmacokinetics of theophylline and produced a constant intestinal clearance that approximated intestinal blood flow.⁸⁸ In 114 hemodialysis patients who received a mean AC daily dose of 3.19 ± 0.81 g/day in three divided doses, mean serum phosphate concentrations decreased by 2.60 ± 0.11 mg/dL, further supporting the concept of "GI dialysis."¹⁴⁶

The toxicokinetic considerations underlying MDAC's ability to enhance elimination are similar to those involved in deciding whether hemodialysis would be appropriate for a given xenobiotic. Successful MDAC requires the xenobiotic to be in the blood compartment (low volume of distribution), have limited protein binding, and have prolonged endogenous clearance. Experimental evidence suggests a role for MDAC in the absence of available Prussian blue (Antidotes in Depth: A28) to treat thallium poisoning.⁵⁵ Although MDAC increases to varying degrees the elimination of amitriptyline, cyclosporine,⁵⁷ carbamazepine,^{16,18,147} dapsone,¹⁰² digitoxin,^{30,117} nadolol,³⁵ nortriptyline, phenobarbital,¹¹⁹ phenylbutazone,¹⁰¹ propoxyphene,⁶⁶ quinine,²⁴ salicylate,^{53,70} and theophylline,^{14,79,138} its clinical utility remains to be defined.^{24,67,137}

An analysis of 28 volunteer studies involving 17 xenobiotics was unable to correlate the physical chemical properties of a particular xenobiotic with MDAC's ability to decrease the plasma half-life of that xenobiotic.²¹ Although the half-life was not thought to be the best marker of enhanced elimination, it was the only parameter consistently evaluated in these exceptionally diverse studies. The xenobiotics with the longest intrinsic plasma half-lives seemed to demonstrate the largest percent reduction in plasma half-life when MDAC was used. A subsequent animal model with therapeutic doses of four simultaneously administered IV xenobiotics (APAP, digoxin, theophylline, and valproic acid) clarified the role of pharmacokinetics on MDAC's effectiveness.²³ Theophylline, APAP, and valproic acid all have small volumes of distribution. However, of the three, only valproic acid is highly protein bound at the doses used, which probably accounted for MDAC's inability to increase its clearance while increasing clearance of the three other xenobiotics. MDAC's most rapid and dramatic effect was on theophylline clearance. Large volumes of distribution alone may not exclude MDAC benefit. Although digoxin has a large volume of distribution, it requires several hours to distribute from the blood to the tissues. MDAC is beneficial as long as the digoxin remains in the blood compartment and distribution is incomplete. However, volunteer studies do not accurately reflect the overdose situation⁸⁹ in which saturation of plasma protein binding, saturation of first-pass metabolism, and acid-base disturbances may make more free xenobiotic available for an enteroenteric effect and therefore more amenable to MDAC use.

In one case series of infants with aminophylline and theophylline overdoses, MDAC appeared to reduce theophylline half-lives (2–12 hours) compared with historical values.¹³⁰ MDAC added as an adjunct to phototherapy in neonatal hyperbilirubinemia produced a significantly greater decline in bilirubin concentrations than in those receiving phototherapy alone.⁵ In a randomized clinical study, phenobarbital overdose patients were given SDAC or MDAC.¹¹⁹ Although the phenobarbital half-life was significantly decreased in the MDAC group (36 vs. 93 hours), the length of intubation time required by each group did not differ from one another. This study was criticized for small size, unevenly matched groups, and focus on a single endpoint (extubation) potentially dependent on factors other than patient condition (eg, the time of day). In 15 adult patients with supratherapeutic phenytoin concentrations, MDAC reduced the time to phenytoin concentration less than 25 mg/L from 41.1 to 19.3 hours, although clinical endpoints were again unchanged.¹³³ A compelling demonstration of MDAC's benefits in the overdose setting comes from a study performed in Sri Lanka in patients with severe cardiac toxicity caused by intentional overdose with yellow oleander seeds.³¹ An initial AC dose of 50 g was administered to all patients, who were then randomized to 50 g of AC every 6 hours for 3 days or placebo. There

were statistically fewer deaths and fewer life-threatening dysrhythmias in the MDAC group. Subsequent randomized, controlled trials further evaluated no AC, SDAC, and MDAC in self-poisoned patients. In 104 patients ingesting yellow oleander seeds, despite erratic and prolonged absorption, SDAC and MDAC significantly and equivalently reduced cardiac glycoside 24-hour mean residence time (which quantifies the time course of a xenobiotic through the body) from 11.21 ± 1.55 hours (no AC) to 10.36 ± 1.14 hours (SDAC) and 10.20 ± 0.99 hours (MDAC), respectively, and apparent terminal half-life from 62.9 hours (no AC) to 33.9 hours (SDAC) and 32.3 hours (MDAC), respectively.¹²³ Despite this, neither SDAC nor MDAC reduced the mortality rate among 4629 randomized, poisoned patients.³⁶ About one-third of the patients had ingested yellow oleander seeds, and slightly less than one-third ingested pesticides. It is unclear how these trials apply to management in developed countries, where the use of antidotes such as digoxin-specific antibody fragments for cardioactive steroid poisoning and atropine and pralidoxime for organic phosphorous pesticide poisoning routinely complement GI decontamination, and the absorption kinetics of most prescription medications differ from the substances ingested in the trial.⁶³ A systematic review concluded that MDAC could enhance phenobarbital or primidone elimination in severe poisonings, although supportive care is the relevant clinical intervention.¹²²

Ultimately, the decision to administer SDAC or MDAC will need to balance the particular ingested xenobiotic, its quantity and the formulation; the xenobiotic's dose-response curve; SDAC's or MDAC's impact on this curve; the time since ingestion; co-ingestants; available antidotes, therapies, and medical support; severity of presentation; anticipated sequelae; patient cooperativity; and other patient-specific factors (eg, age) against potential adverse effects.^{63,110,135}

ADVERSE EFFECTS AND SAFETY ISSUES

Contraindications to AC include presumed GI perforation and the need for endoscopic visualization (eg, caustic ingestion). To prevent aspiration pneumonitis from oral AC administration, an airway assessment must occur and potential airway compromise be excluded. Subsequently, a risk-to-benefit assessment with regard to the need for airway protection and the need for AC should be made. Other considerations include a determination of adequate GI motility (appropriate bowel sounds to ensure peristalsis) and normal abdominal examination findings, and absent distension or signs of an acute abdomen. With compromised bowel function, AC should be withheld or delayed until the stomach can be decompressed to decrease the risk of subsequent vomiting and aspiration.

Although the use of AC is relatively safe, emesis, which typically occurs after rapid administration; constipation; and diarrhea frequently occur after AC administration.¹⁰⁴ Constipation and diarrhea are more likely to result from the ingestion itself than from the AC. However, black stools that are negative for occult blood, black tongues, and darkened mucous membranes are frequently observed. Serious adverse effects of AC include pulmonary aspiration of AC with or without gastric contents, leading to airway obstruction, acute respiratory distress syndrome, bronchiolitis obliterans, and death;^{9,39,44,46,50-52,65,91,100,112,116,131} peritonitis from spillage of enteric contents, including AC, into the peritoneum after GI perforation;⁸³ and intestinal obstruction and pseudo-obstruction, especially after repeated AC doses in the presence of either dehydration or prior bowel adhesions.^{19,47,78,93,121,148} Although a significant number of patients aspirate gastric contents before endotracheal intubation and AC administration,^{95,125} the incidence of AC aspiration after endotracheal intubation was reported to vary from 4% to 25%, depending on the nature of the study. Another retrospective investigation demonstrated a 1.6% incidence of aspiration pneumonitis in unselected overdosed patients. Altered mental status, spontaneous emesis, and tricyclic antidepressant overdose were associated risk factors; AC was not in itself a risk factor.⁶¹ The package insert warns against administration in patients with a genetic intolerance to fructose.¹¹²

Adverse Effects of Multiple-Dose Activated Charcoal

Complications observed with SDAC increase with MDAC. Other adverse effects of MDAC include diarrhea when multiple sorbitol-containing charcoal preparations are used, constipation, vomiting with a subsequent risk of aspiration, intestinal obstruction, and a reduction of serum concentrations of therapeutically used xenobiotics.^{34,93,100,116} One retrospective review of 834 patients receiving MDAC found clinically significant pulmonary aspiration in 0.6%, hypernatremia in 6.0%, and hypermagnesemia in 3.1%.³⁴ Multiple sorbitol-containing charcoal preparations may produce dehydration, hypotension, and potentially fatal electrolyte derangements, especially in children.^{40,96}

PREGNANCY AND LACTATION

Activated charcoal's pregnancy category is undetermined. The benefit of preventing absorption with AC should outweigh the risk of administration to the pregnant patient. The underlying elevated prevalence of nausea and vomiting in pregnancy⁷¹ might predispose pregnant patients to a potentially higher rate of vomiting, although this is speculative. AC has been safely administered to pregnant patients as part of poisoning management.^{22,87,126} Murine and lapine studies have not demonstrated any teratogenic risk.¹¹²

Activated charcoal's lack of absorption would not predispose it to breast milk excretion, although definitive safety in lactation has not been established.¹¹²

DOSING AND ADMINISTRATION

Activated charcoal should not be routinely administered to all poisoned or overdosed patients. SDAC should be administered when a xenobiotic is still expected to be available for adsorption in the GI tract and the benefit of preventing absorption outweighs the risk. The optimal SDAC dose is unknown.²⁴ However, most authorities recommend a minimum AC dose of 1 g/kg of body weight or a 10:1 ratio of AC to xenobiotic, up to an amount that can be tolerated by the patient and safely administered if the dose is known, which usually represents 50 to 100 g in adults. For some ingestions (eg, salicylate or APAP), a 10:1 ratio would be impracticable to achieve, although the 1-g/kg dose may still be efficacious. This is supported by volunteer studies of supratherapeutic ingestions.^{48,64} AC that is not premixed is best administered as a slurry in a 1:8 ratio of AC to suitable liquid, such as water or cola.

Prehospital Administration

Prehospital AC administration by emergency medical technicians and paramedics may expedite the administration after overdose.^{4,149} However, the costs of implementation of such a program would have to be weighed against the small number of patients who would actually benefit.⁶⁰ In a study simulating home administration in 50 young children, 86% readily drank the AC–water slurry, and 76% of them consumed 95% to 100% of the total dose.²⁰ Of seven children in a simulated home environment administered AC in regular cola, three drank 1 g/kg, two drank about half of this therapeutic dose, and the other two drank very little.¹²⁷ A prospective poison center case series demonstrated successful home AC administration. In this series, the median age of the patients was 3 years, and the median AC dose ingested was 12 g.¹³⁶ However, other attempts at getting children to ingest AC were not as successful. Difficulty was noted in 70% of attempts to administer a standard AC dose to children in the home setting.³³ A review of AC in the home suggested variable success depending on the parent and child.³⁸ A retrospective review of poisoned children concluded that those who were preannounced to an emergency department by the poison center received AC earlier (59 ± 34 minutes) than patients without a referral (71 ± 43 minutes).¹⁴⁰

Hospital Administration

Administration may be facilitated by offering children an opaque, decorated, covered cup and a straw.¹⁵⁰ AC's black color and gritty nature has led to the development of many formulations to improve palatability and patient acceptance. Bentonite, carboxymethyl cellulose, and starch^{49,98,128} are used as thickening agents, and cherry syrup, chocolate syrup, sorbitol, sucrose, saccharin, and ice cream have been used as flavoring agents.^{27,77,82,151} Most additives do not decrease the adsorptive capacity; however, improvement in palatability and acceptance has been minimal or nonexistent with all of these formulations.²⁶ Although a milk chocolate AC formulation evaluated by children was rated superior in palatability to standard AC preparations,³⁷ it was never marketed in the United States. A marketed cherry-flavored AC product was rated by adult volunteers as preferable over plain AC, and a statistically significant larger quantity of the flavored AC was ingested.²⁵ This difference was not maintained in adult overdosed patients; most patients consumed the entire bottle of AC independent of cherry flavoring. Cold cola was used to enhance palatability in volunteer children and adults. Children preferred regular cola over diet cola. The adults rated the cola–charcoal combination preferable to the plain charcoal.^{120,127} Other studies in adult overdosed patients compared different AC brands without additives or flavoring to determine the AC quantity typically ingested.^{17,43} In one study, approximately half of the 50 g of AC offered was ingested, and 7% of the patients vomited.¹⁷ In the other study, 60 g of AC as Liqui-Char or CharcoAid G was offered, and approximately 95% of each formulation was consumed in 20 minutes. There was no difference in the amount consumed even though the palatability of the granular form of AC (CharcoAid G) was rated higher.⁴³

Multiple-Dose Activated Charcoal Administration

An initial AC loading dose should be administered to adults and children in an AC-to-xenobiotic ratio of 10:1 or 1 g/kg of body weight (if the xenobiotic exposure amount is unknown). The correct AC dose and interval for multiple dosing, when it is indicated, is best tailored to the amount and dosage form of the xenobiotic ingested, the severity of the overdose, the potential lethality of the xenobiotic, and the patient's ability to tolerate AC. Benefit should always be weighed against risk. Doses of AC for multiple dosing have varied considerably in the past, ranging from 0.25 to 0.5 g/kg of body weight every 1 to 6 hours to 20 to 60 g for adults every 1, 2, 4, or 6 hours. Some evidence suggests that the total dose administered may be more important than the frequency of administration.^{58,141} In some cases, continuous nasogastric administration of AC can be used, especially when vomiting is a problem.^{42,106,141} After the initial AC loading dose of 1 g/kg, subsequent doses of

0.5 g/kg (~25–50 g in adults) every 4 to 6 hours for up to 12 to 24 hours would appear to be an appropriate regimen in most circumstances.

FORMULATION AND ACQUISITION

Activated charcoal may be supplied in bottles or tubes as a ready-to-use aqueous suspension in multiple doses formulations (eg, suspensions of 15 g, 25 g, and 50 g of AC at a fixed concentration of 208 mg/mL AC).¹¹² The AC suspension may also be premixed with sorbitol (eg, 25 and 50 g AC with 48 or 96 g of sorbitol to yield 208 mg/mL of AC and 400 mg/mL of sorbitol).¹¹² When not premixed, it is recommended to create a slurry of AC in a 1:8 ratio of AC to suitable liquid (eg, water, cola).

SUMMARY

- AC is a very effective, nonspecific adsorbent.
- Absent contraindications, AC should be of benefit to a patient with a potentially life-threatening ingestion of a xenobiotic adsorbable by AC that is expected to be present in the GI tract at the time of administration.
- MDAC is useful to prevent systemic absorption of xenobiotics with a prolonged absorptive phases such as an extended-release formulations.
- In the postabsorptive phase, MDAC may decrease the elimination half-lives of certain xenobiotics.
- Care must be taken to avoid pulmonary aspiration and intestinal obstruction when administering AC and MDAC.
- Home availability of AC should be encouraged in remote locations where prehospital care is not immediately available.^{74,75}

A2 ANTIDOTES IN DEPTH

Whole-Bowel Irrigation and Other Intestinal Evacuants

Silas W. Smith and Mary Ann Howland

INTRODUCTION

To alter xenobiotic pharmacokinetics, the approach to a poisoned patient may include administration of gastrointestinal (GI) evacuants. Selected patients may benefit from minimizing systemic exposure by decreasing GI transit time and increasing rectal expulsion. The most effective process of evacuating the GI tract in poisoned patients is referred to as whole-bowel irrigation (WBI). WBI is typically accomplished using polyethylene glycol with a balanced electrolyte lavage solution (PEG-ELS). A detailed discussion of the merits of WBI in the context of various decontamination strategies is provided in [Chap. 8](#).

HISTORY

In 1625 while endeavoring to recover from febrile “Hungarian disease,” Johann Glauber drank from a well from which he later isolated sal mirabile, now known as sodium sulfate, Na_2SO_4 .⁴⁷ He advocated its use as a purgative and determined a synthetic production method.⁴⁷ In 1675, Nehemiah Grew first observed the presence of a purgative salt in the springs at Epsom, later determined to be magnesium sulfate.¹¹³ Phosphate of soda, called “tasteless purging salt,” was found in the urine by Hellot in 1737 and introduced into clinical practice as a purgative by George Pearson some 50 years later.¹⁰⁷ In 1882 to 1883, Hay reported on a series of experiments that provided the basis for the understanding of the mechanism of action of the saline cathartics. He identified the viscus as the main source of bowel fluid, which was secretory in nature, and established a dose–response principle of decreased time to stool as salt concentrations were increased.^{43,44} PEG was introduced in 1957 as a nonabsorbable marker for the study of human fat, carbohydrate, and protein absorption.¹⁵ Experimental studies of intestinal lavage in normal human subjects appeared in 1968.⁷⁸ In 1973, Hewitt and colleagues reported on WBI in clinical practice, their method of “whole-gut irrigation” with a solution of sodium chloride, potassium chloride, and sodium bicarbonate in distilled water to prepare the large bowel for surgery.⁴⁶ WBI was used therapeutically for poisoning in 1976 in a patient ingesting 300 lead airgun pellets who was unresponsive to oral magnesium sulfate purgation.¹⁴⁷

PHARMACOLOGY

Nomenclature

Xenobiotics that promote intestinal evacuation are referred to as laxatives, cathartics, purgatives, promotility agents, and evacuants. Depending upon dose, the same xenobiotic may accomplish some or all of these tasks, with differing side effect profiles. Laxatives promote a soft-formed or semifluid stool within 6 hours to 3 days. Cathartics promote a rapid, watery evacuation within 1 to 3 hours.¹¹⁹ The term purgatives relates the force associated with bowel evacuation. Evacuants are commonly used for pre-procedural bowel cleansing, with an onset of action of as little as 30 to 60 minutes, but typically require 4 hours for a more complete effect. Promotility agents stimulate GI motor function via the enteric nervous system via acetylcholine, serotonin, motilin, or intestinal chloride channels.

Laxatives are further classified into categories of bulk forming, softener or emollient, lubricant, stimulant or irritant, saline, hyperosmotic, and evacuant. Bulk-forming agents include high-fiber products such as methylcellulose, polycarbophil, and psyllium; softeners or emollients include docusate calcium. Mineral oil is the sole lubricant. None of these cathartics is used therapeutically in medical toxicology because their onset of action is delayed. Stimulant or irritant laxatives include anthraquinones (sennosides, aloe, and casanthranol), diphenylmethane (bisacodyl), and castor oil. Saline (meaning salt) cathartics, which include magnesium citrate, magnesium hydroxide, magnesium sulfate, sodium phosphate,

and sodium sulfate, are used infrequently. Hyperosmotic agents, generally nonabsorbable sugars and alcohols including sorbitol and lactulose, are occasionally considered in poisoned patients. The most common process of evacuating the intestinal tract in poisoned patients is WBI.

Chemistry and Preparation

Magnesium citrate ($C_6H_6MgO_7$) and magnesium sulfate ($MgSO_4$, “Epsom salt”) are water-soluble salts of magnesium; magnesium hydroxide ($Mg\{OH\}_2$, “milk of magnesia”) is insoluble.⁵⁶ Sodium sulfate can be prepared through purification of naturally occurring brine deposits or other manufacturing processes. Sodium phosphate is supplied as a combination of the monobasic monohydrate ($NaH_2PO_4 \cdot H_2O$) and dibasic anhydrous (Na_2HPO_4) forms. D-Sorbitol ($C_6H_{14}O_6$), an isomer of mannitol, is a hexitol naturally occurring in many fruits and is produced commercially by the reduction of glucose. Lactulose is a water-soluble, synthetic disaccharide, 4-O- β -D-galactopyranosyl-D-fructofuranose.

The addition reaction of ethylene oxide (C_2H_4O) to an ethylene glycol equivalent creates ethylene oxide polymerization into polyethylene glycol (PEG). The “n” in the molecular structure of PEG, $H-(OCH_2CH_2)_n-OH$ refers to the average number of repeating oxyethylene groups.⁶⁰ The number after PEG represents its average molecular weight (MW). PEG, also known as macrogol, has numerous medicinal applications. It can be conjugated to pharmaceuticals to delay vascular clearance (“PEGylation”), serve as a solvent in oral liquids and soft capsules, function as a nonalcohol solubilizer and diluent for liquid oral-dose medications, provide a base for medical ointment and cosmetics, and act as a base liquid for producing vapor in electronic cigarettes.¹⁰³ Low-molecular-weight PEG (eg, 300 or 400 Da), because of its advantageous solvent properties, is used to decontaminate phenol burns, although animal studies demonstrated the equal efficacy of copious (deluge) quantities of water.⁵¹ Higher-molecular-weight variants are used to promote laxation. Although PEG’s physical properties (eg, water solubility, hygroscopicity, vapor pressure, melting or freezing range, and viscosity) vary with MW and blending because of chain-length effects, the chemical properties are similar.¹³¹ PEG 3350 used in pharmaceutical, personal care, and food applications is water soluble. It has a MW range of 3015 to 3685 Da, an average number of 75.7 repeating oxyethylene units, a pH of a 5% aqueous solution of 4.5 to 7.5 at 25°C, a density of 1.09 g/cm³ at 60°C, a melting or freezing range between 53° and 57°C, a water solubility of 67% by weight at 20°C, and a viscosity of 90.8 centistokes at 100°C.^{130,132} PEG 3350 without electrolytes is sold for nonprescription use for short-term constipation treatment. WBI used in poison management is typically accomplished using PEG 3350 added to a balanced electrolyte lavage solution (PEG-ELS), which contains an isotonic mixture of sodium sulfate, sodium bicarbonate, sodium chloride, and potassium chloride.¹¹⁹

Mechanisms of Action

The effects of saline cathartics are largely attributed to their relatively nonabsorbable ions that establish an osmotic gradient and draw water into the gut.¹⁰⁴ The increased water leads to increased intestinal pressure and a subsequent increase in intestinal motility. Magnesium ions also lead to the release of cholecystokinin from the duodenal mucosa, which stimulates intestinal motor activity and alters fluid movement, contributing to catharsis.^{14,119,126} A lack of endogenous hydrolytic enzymes allows sorbitol and lactulose to reach the colon unchanged. Colonic bacteria metabolize sorbitol into acetic and other short chain fatty acids and lactulose into lactic acid and small amounts of formic and acetic acids. This results in a slight acidification of colonic contents, an increase in osmotic pressure that draws water into the lumen, and stimulation of colonic propulsive motility.¹¹⁹

Long-chain PEGs (eg, MW ~3350 Da) are nonabsorbable, isoosmotic, indigestible molecules that remain in the colon together with the water diluent, resulting in WBI primarily by the mechanical effect of large-volume lavage. The added balanced electrolyte solution practically eliminates electrolyte abnormalities and helps preclude fluid shifts across the GI mucosa. Sodium sulfate in many preparations reduces sodium absorption in the small intestine because of the absence of chloride, the accompanying anion necessary for active absorption against the electrochemical gradient.⁸³

Promotility agents such as metoclopramide and erythromycin stimulate gut motor function. Metoclopramide mediates GI 5-HT₄ receptor agonist and D₂ receptor antagonist activity, which both result in increased acetylcholine release and GI motility. Erythromycin also stimulates gut motor function but via direct stimulation of GI motilin receptors.¹³⁹ Lubiprostone is a promotility drug that stimulates chloride secretion and enhances the contraction of gastric and colonic musculature.⁶¹ Although lubiprostone has been used with WBI for the treatment of constipation, their combined use has not yet been reported in poisoned patients.

Pharmacokinetics

Absorption of magnesium, phosphate, and other electrolytes contained in hypertonic products is well described and may risk morbidity.^{27,98,104} In one prospective, nonrandomized study, nine of 14 patients developed elevated magnesium concentrations (2.2–5.0 mEq/L) after multiple doses of magnesium-containing cathartics for suspected drug overdose

despite normal blood urea nitrogen and creatinine values.¹²³ During the 24 hours after administration of oral sodium phosphate solution in seven healthy volunteers, serum phosphorus reached a mean peak of 7.6 mg/dL (range, 3.6–12.4 mg/dL), and ionized calcium reached a mean nadir 4.6 mg/dL (range, 4.4–5.2 mg/dL).²⁷

By virtue of its high osmotic nature long-chain PEG is poorly absorbed, is retained in the lumen, and does not distribute. PEG is therefore eliminated unmetabolized in rectal effluent.

Pharmacodynamics

Patients ingesting 45 mL of an aqueous sodium phosphate preparation taken the evening before and the morning of a procedure initiated bowel activity within 1.7 hours of the first dose and within 0.7 hours of the second dose, with a mean duration of activity of 4.6 and 2.9 hours, respectively, and an end of bowel activity within 4 to 5 hours.⁷⁴ In six volunteers, saline cathartics decreased activated charcoal (AC) mean GI transit time from 29.3±1.2 hours to 24.4±1.2 hours, 15.4±3.0 hours, 17.3±1.9 hours, and 17.5±2.3 hours with sodium chloride, sodium sulfate, magnesium sulfate, and a proprietary cathartic “salt” (36.7% anhydrous citric acid, 17.65% magnesium sulfate, and 45.6% sodium bicarbonate), respectively.¹⁰⁵ When different cathartics were compared with respect to time to first stool and number of stools,^{54,68,96,97,127} sorbitol produced 10 to 15 watery stools and the most abdominal cramping before catharsis. Sorbitol produced stools in the shortest amount of time, which also was associated with the highest incidence of nausea, vomiting, generated gas, and flatus.^{62,64,99} In one systematic review, mean transit times after administration of sorbitol, magnesium citrate, magnesium sulfate, and sodium sulfate were 0.9 to 8.5 hours, 3 to 14 hours, 9.3 hours, and 4.2 to 15.4 hours, respectively.⁵ In comparison, the first bowel movement typically occurs relatively quickly after the initiation of WBI with PEG-ELS. Patients ingesting GoLYTELY (1.2–1.8 L/h until the rectal effluent was clear) completed their colonic preparation within 1.5 to 3 hours after averaging a total of 5.5 L per patient (range, 3–8 L).³⁹

ROLE OF GASTROINTESTINAL EVACUATION IN POISONING MANAGEMENT

Although recommended for basic poison management for many years, cathartics should not be used routinely in the management of overdosed patients.⁵ Intuitively, the advantages of cathartics appear to result from their ability to decrease the potential for constipation or obstruction from AC and hasten the delivery of AC to the small intestine. However, these theoretical advantages have never been demonstrated clinically.

Studies demonstrate that when administered alone, cathartics such as sorbitol or sodium sulfate may decrease peak or total absorption of some xenobiotics, but no study of cathartics alone has achieved results comparable to that of AC alone.^{2,24,88,108,141} When comparing the efficacy of a single dose of AC alone with that of AC plus a single dose of cathartic, studies suggest the combination to be equal to,^{2,93,102,122} slightly better than,^{24,62} or even slightly worse than AC alone.^{88,141} WBI with PEG-ELS is currently advocated to hasten the elimination of poorly absorbed xenobiotics or sustained-release medications before they can be absorbed. This approach is theoretically sound and does not produce the fluid and electrolyte complications associated with cathartics. Unfortunately, evidence of efficacy is limited to anecdotal case reports and volunteer studies.

Many studies of WBI using PEG-ELS demonstrate patient acceptance, effectiveness, and safety when used for bowel preparation, its labeled indication.^{4,12,16,17,28,31,32,109,133,136} Animal models suggest that WBI may enhance systemic clearance via GI dialysis, similar to multiple-dose activated charcoal (MDAC).⁷³ In actuality, low flow rates, the typical delay in administering WBI in actual clinical situations, and the inconvenience of this procedure make it highly unlikely that enhanced systemic clearance can be achieved in humans. In human volunteer studies, WBI was more effective than AC with sorbitol for enteric-coated acetylsalicylic acid (ASA) when administered 4 hours after ingestion,⁶⁴ decreased peak lithium concentrations, and lithium AUC (area under the plasma drug concentration vs. time curve) compared with control participants;¹²⁴ decreased the bioavailability of two sustained-release medications;^{21,71} and propelled radiopaque markers through the gut more efficiently than control participants.⁸⁰ In a retrospective analysis of 59 acute-on-chronic lithium overdoses, those decontaminated at an early stage with sodium polystyrene sulfonate, WBI, or both achieved statistically significant and clinically relevant decreases in peak serum lithium concentrations compared with those with delayed (>12 hours) or no decontamination (2.39 vs. 4.08 mEq/L).¹⁸ A retrospective chart review of 176 pediatric cases in a state electronic database from 2000 and 2010 documented WBI use in 72 cases involving sustained- and delayed-release medications, such as nifedipine, bupropion, verapamil, diltiazem, and felodipine.⁷⁵ Abdominal radiographs were performed in 36 cases, of whom 16 had demonstrable radiopaque pills. Four of these had repeat abdominal radiographs, all of which demonstrated a decrease in opacities.

Not unexpectedly, WBI was inferior to AC with regard to prevention of absorption when administered after 650 mg of immediate-release aspirin.¹¹² Additionally, after the aspirin was absorbed, WBI was unable to enhance systemic

clearance.⁸⁷ Likewise, only a small, statistically insignificant effect of WBI could be demonstrated on the absorption of extended-release acetaminophen in a human volunteer study.⁸⁰ These findings highlight the limited utility of WBI to assist in the prevention of absorption of relatively rapidly absorbed xenobiotics. Reports have shown successful WBI use in the management of overdoses of iron,^{33,59,85,128,129} sustained-release theophylline,⁵⁵ sustained-release verapamil,¹⁹ modified-release fenfluramine,⁹⁵ zinc sulfate,²⁰ lead,^{92,94,116,147} arsenic trioxide,⁵³ arsenic-containing herbicide,⁷² mercuric oxide powder,⁸¹ strontium,⁶³ potassium chloride capsules,^{42,50} and clonidine and fentanyl transdermal patches^{36,52} and in body packers.^{49,134,138} Although some clinicians express enthusiasm for the use of WBI for a variety of ingestions, others question its efficacy.^{20,114} WBI for 5 hours after ingestion of 10 fluorescent coffee beans by each of seven volunteers removed an average of only four beans (range, 1–8).¹¹⁴ Similar failures are reported with jequirity beans,²⁰ iron,^{23,142} and button batteries.¹²⁸ It can be argued that because of physical characteristics (eg, density, solubility, size, or pharmacobezoar formation), these cases might not be representative of xenobiotics amenable to WBI.

Internal Drug Concealment

The approach to patients with internal concealment and enteral transport of illicit substances (eg, cocaine, heroin, amphetamines, and hashish) is comprehensively reviewed in Special Considerations: SC5. Close coordination with surgical services is advised because of the risks of obstruction, intestinal retention, or rupture. Mineral oil rapidly degrades latex condoms.¹⁴⁴ Use of mineral oil in evacuating drug packets, which may be constructed in this fashion, risks fatal rupture.¹⁴³ In a retrospective descriptive case series of 16 body packers, conservative management with WBI was successful in 14; a ruptured cocaine packet produced mild toxicity in one patient, and packets were retained in one of the heroin body packers.³⁵ In another retrospective analysis of 34 cocaine body stuffers who were asymptomatic on presentation, one received WBI alone, and 19 received WBI plus AC and remained asymptomatic and were discharged after 24 hours.⁵⁸ A review of 1250 confirmed body packers found the success rate of a conservative management strategy of WBI to be 98%.⁸⁴ All conservatively managed patients passed all of their packets within 5 days. WBI may not always evacuate all of the drug packets because of inadequate dosing, partial obstruction, or the nature of the procedure. In one case, prolonged WBI failed to clear a methamphetamine body stuffer who engaged in “parachuting.”⁴⁵ As a result of these failures, promotility agents were added to WBI and presumably successfully enhanced bowel evacuation in two body packers suspected of having ingested well-constructed drug packets.¹³⁵

ADVERSE EFFECTS AND SAFETY ISSUES

Potential adverse effects associated with various cathartics and promotility agents include dehydration, hypokalemia and metabolic alkalosis from dehydration, absorption of magnesium or other absorbable electrolytes, activation of the renin–angiotensin–aldosterone system, phosphate-induced nephropathy, and colonic fermentation of digestible sugars.^{22,37,121} Cathartic-induced rectal prolapse is reported in geriatric patients.⁶⁶ The use of repetitive doses of cathartics, either by design or unintentionally, has led to hypermagnesemia, altered mental status, and death.^{57,98,123,146} Hypocalcemia, hyperphosphatemia, and hypokalemia have accompanied the use of hypertonic phosphate enemas and oral sodium phosphate despite adherence to recommended dosing.^{29,37,41,77,86,110,125} Frail elderly patients, children, and those with decreased kidney function may be most susceptible to adverse effects.^{11,13}

Softeners may increase intestinal permeability and therefore increase the absorption of some xenobiotics.^{9,119} Mineral oil risks enhanced absorption of lipid-soluble xenobiotics, lipid pneumonia in the event of aspiration, and rupture of concealed drug packets packaged in latex.¹⁴³ Stimulant and irritant laxatives are rarely used today in medical toxicology because of their significant GI side effects, including abdominal discomfort, cramping, and tenesmus and with chronic administration, bowel habituation and intestinal tissue damage.

Contraindications to WBI include prior, current, or anticipated diarrhea; volume depletion; significant GI anatomical or functional compromise such as colitis, hemorrhage, ileus, obstruction, perforation, or toxic megacolon; an unprotected or compromised airway; and hemodynamic instability.^{6,128}

MDAC regimens containing 70% sorbitol used to enhance elimination resulted in severe cathartic-related adverse effects in several case reports.^{3,34,76,89} The potential for sorbitol-related adverse events from the unintentional use of repetitive AC dosing was emphasized by a survey revealing that 16% of hospitals surveyed only stocked AC premixed with sorbitol.¹⁴⁵ The retention of sorbitol after repetitive doses in an aperistaltic gut may lead to significant morbidity from gas formation and abdominal distention as a result of the digestive action of gut bacteria.⁷⁶

Adverse effects resulting from the use of WBI with PEG-ELS include vomiting, particularly after rapid administration, abdominal bloating, fullness, cramping, flatulence, and pruritus ani. Of the 176 pediatric cases detailed in the California Poison Control System electronic database, 16 vomited, and one experienced abdominal pain.⁷⁵ In an alternative administration strategy in which 46 children were provided 238 g of PEG-3350 mixed with 1.9 L of Gatorade, complaint

rates of nausea and vomiting, abdominal pain and cramping, and fatigue and weakness were 60%, 44%, and 40%, respectively.¹ Typically, patients need to remain near a commode for 4 to 6 hours to complete WBI therapy. Slow or low-volume administration of PEG-ELS results in sodium absorption. If a total of 500 mL of PEG-ELS was used instead of multiple liters, potentially 1.5 g of sodium may be absorbed.³⁰ This adverse effect might have resulted in the exacerbation of congestive heart failure in an unstable patient with cardiac and renal dysfunction.⁴⁰ An unusual complication of WBI is colonic perforation, which occurred in a patient with active diverticulitis.⁷⁰ Other adverse effects noted by the manufacturer include isolated reports of upper GI bleeding from a Mallory-Weiss tear, esophageal perforation, aspiration pneumonitis after vomiting, and ARDS. Rare cases of both hypo- and hypernatremia, leading to altered consciousness, seizures, cerebral edema, and death, are reported with PEG, alone or in combination with ELS.^{10,100,115}

Unintentional administration of PEG-ELS by other than the enteral route has occurred. A 4 year-old child inadvertently received 390 mL of PEG-ELS intravenously with no obvious adverse result.¹¹¹ In contrast, acute respiratory distress syndrome (ARDS) developed in an 11 year-old child administered PEG-ELS through a nasogastric tube inadvertently inserted in the trachea.¹⁰¹ In a similar case, a poorly placed nasogastric tube was responsible for PEG-ELS aspiration in a 3 year-old boy, with resultant hypoxia and hemodynamic instability requiring endotracheal intubation.³⁸ An 8 year-old girl with emesis during nasogastric infusion of 1 L of PEG-ELS experienced gagging, coughing, and emesis, and respiratory distress 2 hours after infusion, resulted in ARDS and requiring intubation and ventilatory support for 2 days.¹⁰⁶ A report of two cases suggests that vomiting and aspiration may be more frequent than previously recognized in hemodynamically unstable patients.²⁶ Presumably, a patient's hypotension results in GI hypoperfusion and ileus, which, with the continued administration of WBI in the presence of decreased GI motility, produces abdominal distention and vomiting.

For MiraLax to be useful in WBI, it would need to be administered at a dose of 2 L/h (8 heaping teaspoons in 2 L of water/h) in adults. This is not recommended for WBI because it does not contain any added electrolytes and could result in an electrolyte imbalance and shifts.

Activated Charcoal and Whole-Bowel Irrigation Interactions

Several in vitro studies (with cocaine, chlorpromazine, fluoxetine, salicylate, and theophylline) demonstrate that the addition of PEG-ELS to AC significantly decreases the adsorptive capacity of AC.^{7,8,48,65,82} Some interactions were affected by pH and magnified by high ratios of PEG-ELS to AC.^{8,65,82} The most likely explanation is competition with the AC surface for solute adsorption. Additionally, in an animal model, WBI appeared to have an adverse effect by washing the AC away from the sustained-release theophylline.²¹ One controlled study evaluated the effect of WBI added to 25 g of AC in nine healthy human volunteers simultaneously ingesting 200 mg of carbamazepine, 200 mg of theophylline, and 120 mg of verapamil.⁷¹ Compared with AC alone, WBI provided with AC significantly decreased verapamil peak concentration (C_{max}) and AUC but significantly increased carbamazepine C_{max} and AUC and nonsignificantly increased theophylline C_{max} and AUC. One case report documents rapid increases in carbamazepine concentrations temporally related to the initiation of WBI.⁷⁹ Although the patient had received MDAC and hemoperfusion, xenobiotic concentrations were increasing 58 hours after ingestion. It is possible that PEG-ELS competed for carbamazepine binding to AC, displacing some drug and making it available for absorption. A similar rapidly increasing drug concentration was noted after the initiation of WBI in a patient with a reported 10-g phenytoin overdose.²⁵ In this case, AC had not been given before the initiation of WBI. One possible explanation is that the massive dose of phenytoin prevented its own absorption by exceeding its solubility, but the administration of WBI provided sufficient diluent to allow phenytoin dissolution before GI emptying with subsequent absorption. One human study evaluated the influence of various decontamination strategies on the probability of seizures in 319 patients who overdosed on venlafaxine on 436 occasions.⁶⁹ WBI added to AC alone in a mean ingestion of 2100 mg further reduced the odds ratio (OR) of a seizure to 0.25 (0.08–0.62) compared with an OR of 0.48 (0.25–0.89) with AC alone. Most of these patients ingested extended-release venlafaxine. Their results demonstrated that combining AC and WBI provided a greater benefit than the sum of the independent effects of single-dose activated charcoal (SDAC) and WBI and argued against adverse clinical effects caused by desorption in venlafaxine ingestion.⁶⁹

PREGNANCY AND LACTATION

Commercial preparations of PEG-ELS are pregnancy category C.^{16,17,117,118} Animal reproduction studies have not been conducted with Colyte, GoLYTELY, NuLYTELY, or TriLyte.^{16,17,117,118} The underlying elevated prevalence of nausea and vomiting in pregnancy⁶⁷ might predispose pregnant patients to vomit more frequently, although this is speculative. WBI with large volumes of fluid has been used successfully in pregnant women at 26 and 38 weeks of gestation.^{137,140} The lack of absorption PEG-ELS would not predispose it to excretion in breast milk, although definitive safety in lactation is not established.

DOSING AND ADMINISTRATION

The usual nonprescription daily dose for the short-term treatment (2 weeks) of occasional constipation is 17 g of powder in 8 oz (240 mL) of water. The recommended dose of WBI with PEG-ELS solution is considerably larger: 0.5 L/h or 25 mL/kg/h for small children and 1.5 to 2.0 L/h or 20 to 30 mL/min for adolescents and adults. WBI solution may be administered orally or through a nasogastric tube for 4 to 6 hours or until the rectal effluent becomes clear. An antiemetic such as metoclopramide or a 5-HT₃ serotonin antagonist may be required for the treatment of nausea or vomiting. In select patients, promotility agents may serve as useful adjuncts.¹³⁵ If the xenobiotic being removed is radiopaque, a diagnostic imaging technique demonstrating the absence of the xenobiotic may serve as an initial clinical endpoint (Special Considerations: SC5).

FORMULATION AND ACQUISITION

The original WBI solution was GoLYTELY manufactured by Braintree. This solution contained PEG with electrolytes and sodium sulfate as an added laxative. Colyte is manufactured by Schwartz Pharma and is similar to GoLYTELY. Braintree later introduced NuLYTELY, a PEG formulation with 52% less total salt than GoLYTELY without added sodium sulfate. These changes decreased the salty taste and the risk of fluid- or electrolyte-related complications.⁹⁰ Many products are available with flavors. The available PEG-ELS products are prepared by filling the container to the 4-L (or 1-gal) mark with water and shaking vigorously several times to ensure dissolution. Lukewarm water facilitates dissolution, but subsequent chilling improves palatability. Chilled solutions are not recommended for infants because of hypothermia risk. Products are stable with refrigeration for 48 hours after reconstitution. Available PEG-ELS products (eg, GoLYTELY, Colyte, NuLYTELY, TriLyte) differ slightly in their composition. All contain PEG 3350 with varying amounts of sodium chloride, potassium chloride, sodium sulfate, and sodium bicarbonate, which upon reconstitution yield sodium, 65 to 125 mEq/L; potassium, 5 to 10 mEq/L; chloride, 35 to 53 mEq/L; bicarbonate, 17 to 20 mEq/L; and sulfate, 0 to 80 mEq/L.^{16,17,117,118}

MiraLax contains electrolyte-free PEG 3350 powder meant for oral administration after dissolution in water, juice, or soda. It is indicated for occasional constipation and not for poisoning management, with a recommended dose of 1 heaping teaspoon (17 g) in 8 oz (240 mL) of liquid per day. However, alternative WBI formulations using electrolyte-free PEG 3350 with Gatorade have been used clinically. One study of 139 patients comparing 4 L of PEG-ELS with electrolyte-free PEG combined with 1.9 L of Gatorade and found no differences in colonoscopy preparation scores, higher overall patient satisfaction scores with the Gatorade mixture, and fewer adverse effects (bloating and nausea).⁹¹ In 46 children provided PEG 3350 mixed with 1.9 L of Gatorade over a few hours, 93.5% completed the regimen, and 77% achieved effective colonic visualization.¹ In a retrospective evaluation of an endoscopic database analysis, patients undergoing bowel preparation using PEG 3350 without electrolytes (238 g of MiraLax in 64 oz of Gatorade) and four 5-mg bisacodyl tablets were more likely to achieve an excellent or good bowel cleansing compared with patients receiving a GoLyteLy preparation (93.3% vs. 89.3%), without any adverse events.¹²⁰

SUMMARY

- Cathartics are not considered part of routine management of poisoning and overdose in children or adults and should not be used as an AC substitute when xenobiotics known to be adsorbed to AC are involved.
- When MDAC is administered, if a cathartic is used at all, it should be provided only with the first dose. Sufficient oral fluids should always accompany cathartic administration to avoid dehydration and inspissation.
- AC should be given to patients for whom it is indicated, and if WBI is being performed in conjunction, a comparable dose of AC should be given after WBI to prevent or overcome the potential desorption and possible further systemic absorption of the xenobiotic.
- Unless contraindicated, WBI is preferable to repetitive dose cathartics for evacuation of sustained-release or poorly soluble xenobiotics not adsorbed to AC.
- WBI's precise role and the interactions between PEG-ELS and AC in overdosed patients remain ill defined. Absent controlled clinical studies to assess outcome, WBI may be considered in ingestions of sustained-release xenobiotics, xenobiotic ingestions with a slow absorptive phase and a high expectation of morbidity; xenobiotics not adsorbed by activated charcoal (eg, iron, lead, lithium); and foreign body ingestions, specifically drug packets in body packers.

9 PHARMACOKINETIC AND TOXICOKINETIC PRINCIPLES

Mary Ann Howland

Pharmacokinetics is the study of the absorption, distribution, metabolism, and excretion of xenobiotics. Xenobiotics are substances that are foreign to the body and include natural or synthetic chemicals, drugs, pesticides, environmental agents, and industrial agents.⁴⁹ Mathematical models and equations are used to describe and to predict these phenomena. Pharmacodynamics is the term used to describe an investigation of the relationship of xenobiotic concentration to clinical effects. Toxicokinetics, which is analogous to pharmacokinetics, is the study of the absorption, distribution, metabolism, and excretion of a xenobiotic under circumstances that produce toxicity. Toxicodynamics, which is analogous to pharmacodynamics, is the study of the relationship of toxic concentrations of xenobiotics to clinical effects.

Overdoses provide many challenges to the mathematical precision of toxicokinetics and toxicodynamics because many of the variables, such as dose, time of ingestion, and presence of vomiting, that affect the result are often unknown. In contrast to the therapeutic setting, atypical solubility characteristics are noted, and saturation of enzymatic processes occurs. Intestinal or hepatic enzymatic saturation or alterations in transporters may lead to enhanced absorption through a decrease in first-pass effect. Metabolism before the xenobiotic reaches the blood is referred to as the first-pass effect.^{2,76} Saturation of plasma protein binding results in more free xenobiotic available in the plasma. Saturation of hepatic enzymes or active renal tubular secretion leads to prolonged elimination. In addition, age, obesity, gender, pharmacogenetics and pharmacogenomics, chronopharmacokinetics (diurnal variations), and the effects of illness and compromised organ perfusion all further inhibit attempts to achieve precise analyses.^{3,17,40,45,68,72} Furthermore, various treatments may alter one or more pharmacokinetic and toxicokinetic parameters. There are numerous approaches to recognizing these variables, such as obtaining historical information from the patient's family and friends, performing pill counts, procuring sequential serum concentrations during the phases of toxicity, and occasionally repeating a pharmacokinetic evaluation during therapeutic dosing of that same xenobiotic to obtain comparative data.

Although different, plasma concentration and serum concentration are terms often used interchangeably. When a reference or calculation is made with regard to a concentration in the body, it is actually a plasma concentration. When concentrations are measured in the laboratory, a serum concentration (clotted and centrifuged blood) is often determined. In reality, the laboratory measurements of most xenobiotics in serum or plasma are nearly equivalent. Frequently, this is not the case for whole-blood determination if the xenobiotic distributes into the erythrocyte, such as lead and most other heavy metals.

Despite all of the confounding and individual variability, toxicokinetic principles may nonetheless be applied to facilitate our understanding and to make certain predictions. These principles may be used to help evaluate whether a certain antidote or extracorporeal removal method is appropriate for use, when the serum concentration might be expected to decrease into the therapeutic range (if one exists), what ingested dose might be considered potentially toxic, what the onset and duration of toxicity might be, and what the importance is of a serum concentration. While considering all of these factors, the clinical status of the patient is paramount, and mathematical formulas and equations can never substitute for a sound clinical assessment. This chapter explains the principles and presents the mathematics in a user-friendly fashion.⁷⁹

ABSORPTION

Absorption is the process by which a xenobiotic enters the body. A xenobiotic must reach the bloodstream and then be distributed to the site or sites of action to cause a systemic effect. Both the rate (k_a) and extent of absorption (F) are measurable and important determinants of toxicity. The rate of absorption often predicts the onset of action and relies on dosage form, and the extent of absorption (bioavailability) often predicts the intensity of the effect and depends in part on first-pass effects.^{36,37} Figure 9–1 depicts how changes in the rate of absorption may affect toxicity when the bioavailability is held constant versus how toxicity may be affected by changes in bioavailability when the rate of absorption is held constant.

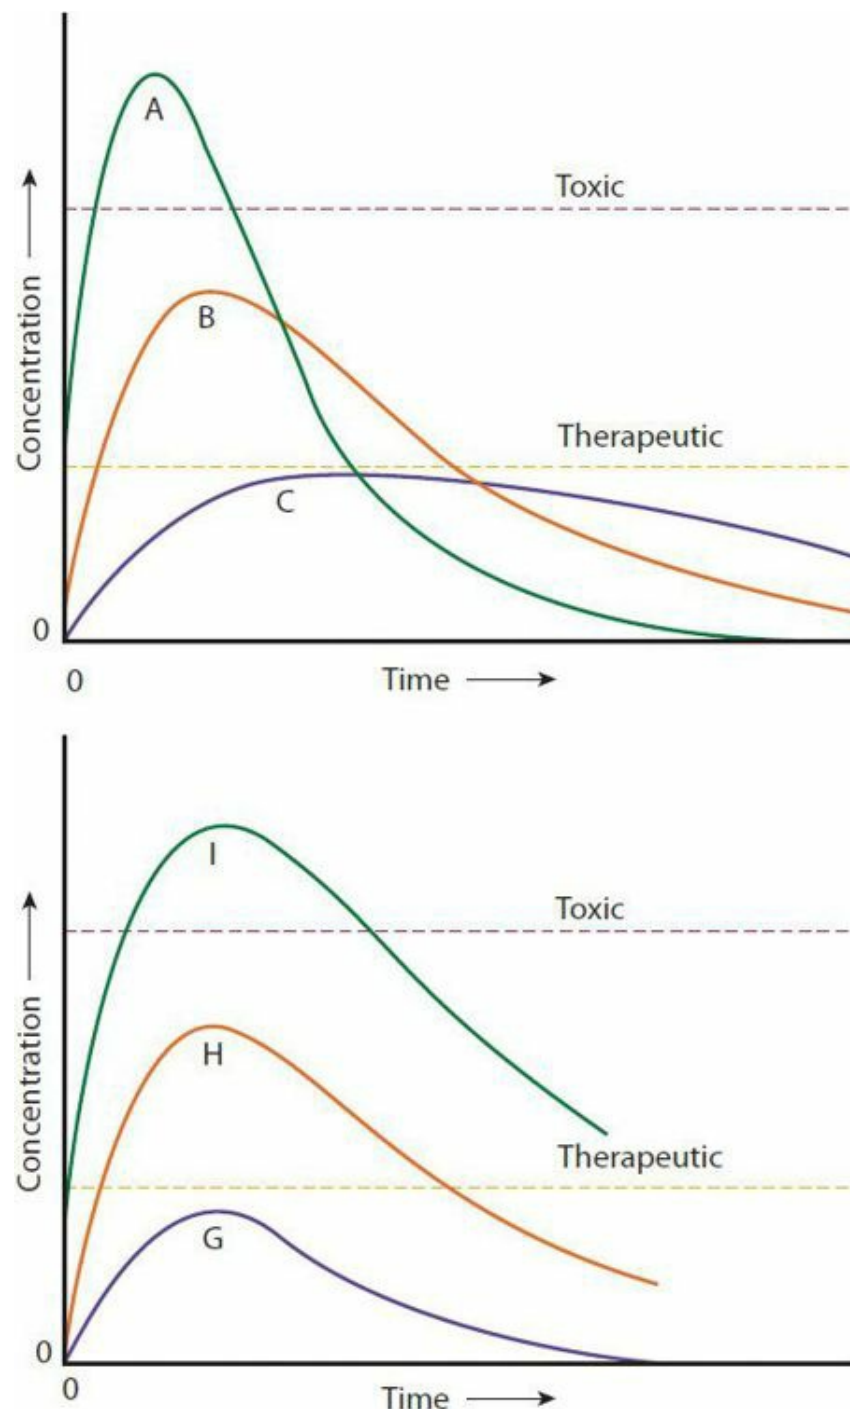

FIGURE 9-1. Effects of changes in k_a (rate of absorption) and F (bioavailability) on the blood concentration versus time graph and achieving a toxic threshold. In curves A, B, and C, F is constant as k_a decreases. In curves G, H, and I, k_a is constant as F increases from G to I.⁵⁴

The route by which the xenobiotic enters the body significantly affects both the rate and extent of absorption. As an approximation, the rate of absorption proceeds in the following order from fastest to slowest: intravenous (IV), inhalation > sublingual > intramuscular, subcutaneous, intranasal, oral > cutaneous, rectal. After the oral intake of 200 mg (0.59 mmole) of cocaine hydrochloride, the onset of action is 20 minutes, with an average peak concentration of 200 ng/mL.⁷¹ In marked contrast, smoking 200 mg (0.66 mmole) of cocaine freebase results in an onset of action of 8 seconds and a peak concentration of 640 ng/mL. When administered IV as 200 mg cocaine hydrochloride, it then has an onset of action of 30 seconds and a peak concentration of 1000 ng/mL.⁷¹

A xenobiotic must diffuse through a number of membranes before it can reach its site of action. Figure 9-2 shows the number of membranes through which a xenobiotic typically diffuses. Membranes are predominantly composed of phospholipids and cholesterol in addition to other lipid compounds.⁵⁴ A phospholipid is composed of a polar head and a fatty acid tail, which are arranged in membranes so that the fatty acid tails are inside and the polar heads face outward in a mirror image.⁵⁸ Proteins are found on both sides of the membranes and may traverse the membrane.⁵⁴ These proteins may function as receptors and channels. Pores are found throughout the membranes. The principles relating to diffusion apply to absorption, distribution, certain aspects of elimination, and each mechanism that permits a xenobiotic to be transported through a membrane.

FIGURE 9-2. Illustration of the number of membranes encountered by a xenobiotic in the process of absorption and distribution and the transport mechanisms involved in the passage of xenobiotics across membranes. Examples include diffusion: nonelectrolytes (ethanol) and nonionized forms of weak acids (salicylic acid) and bases (amphetamines); endocytosis: Sabin polio virus vaccine; facilitated: 5-fluorouracil, lead, methyldopa, thallium; and active: thiamine and pyridoxine.

Transport through membranes occurs via (1) passive diffusion; (2) filtration or bulk flow, which is most important in renal and biliary secretion as the mechanism of transport associated with the movement of molecules with a molecular weight less than 100 Da, with water directly through aquapores; (3) carrier-mediated active or facilitated transport, which is saturable; and (4) rarely, endocytosis (Fig. 9-2). Most xenobiotics traverse membranes via simple passive diffusion. The rate of diffusion is determined by the Fick's law of diffusion (Equation 9-1):

$$\text{Rate of diffusion} = \frac{dQ}{dt} = \frac{DAK(C_1 - C_2)}{h} \quad (\text{Eq. 9-1})$$

Where:

D = diffusion coefficient

A = surface area of the membrane

h = membrane thickness

K = partition coefficient

$C_1 - C_2$ = difference in concentrations of the xenobiotic on each side of the membrane

The driving force for passive diffusion is the difference between the concentrations of the xenobiotic on the opposing sides of the membrane. D is a constant for each xenobiotic and is derived when the difference in concentrations between the two sides of the membrane is one. The larger the surface area A, the higher the rate of diffusion. Most ingested xenobiotics are absorbed more rapidly in the small intestine than in the stomach because of the tremendous increase in surface area created by the presence of microvilli. The partition constant or ratio (previously called the coefficient) K_{ow} represents the lipid-to-water partitioning of the nonionized xenobiotic with pH adjustment to favor nonionized xenobiotic. To a substantial degree, the more lipid soluble a xenobiotic is, the more easily it crosses membranes. The logarithm of the K_{ow} is known as the log P. The distribution constant or ratio represents the lipid-to-water partitioning of the sum of the nonionized plus ionized in the octanol and water phase and is pH dependent. The logarithm of the distribution constant is called log D and is most useful when measured at physiologic pH. Membrane thickness (h) is inversely proportional to the rate at which a

xenobiotic diffuses through the membrane. Xenobiotics that are uncharged, nonpolar, of low molecular weight, and of the appropriate lipid solubility have the highest rates of passive diffusion.

The extent of ionization of weak electrolytes (weak acids and weak bases) affects their rate of passive diffusion. Nonpolar and uncharged molecules penetrate faster. The Henderson-Hasselbalch relationship is used to determine the degree of ionization. An acid (HA), by definition, gives up a proton, and a base (B) accepts a proton. Acids and bases can be nonionized (uncharged, molecular, free), positively charged (cationic), or negatively charged (anionic). Aspirin and phenobarbital are uncharged acids (RCOOH), and pseudoephedrine HCl is a cationic acid. Morphine, amphetamine, and amitriptyline are nonionized bases (RNH₂), and sodium valproate is an anionic base. The equilibrium dissociation constants K_a and K_b can then be described. $K_a \times K_b = K_w$, and K_w is the dissociation constant of water. Because these numbers are difficult to work with, they are transformed using logarithms. By Equations 9–2A and 9–2B:

$$\text{For weak acids: } HA = H^+ + A^- \quad K_a = \frac{[H^+][A^-]}{[HA]} \quad (\text{Eq. 9-2A})$$

$$\text{For weak bases: } BH^+ = B + H^+ \quad K_b = \frac{[H^+][B]}{[BH^+]} \quad (\text{Eq. 9-2B})$$

To work with these numbers in a more comfortable fashion, the negative log of both sides is determined. The results are given in Equations 9–3A and 9–3B.

$$\text{For weak acids: } -\log K_a = -\log[H^+] - \log \frac{[A^-]}{[HA]} \quad (\text{Eq. 9-3A})$$

$$\text{For weak bases: } -\log K_b = -\log[H^+] - \log \frac{[B]}{[BH^+]} \quad (\text{Eq. 9-3B})$$

By definition, the negative log of $[H^+]$ is expressed as pH, and the negative log of K_a is pK_a . Rearranging the equations gives the familiar forms of the Henderson-Hasselbalch equations, as shown in Equations 9–4A, 9–4B, and 9–4C:

$$pH = pK_a + \log \frac{\text{Unprotonated species}}{\text{Protonated species}} \quad (\text{Eq. 9-4A})$$

$$\text{For weak acids: } pH = pK_a + \log \frac{[A^-]}{[HA]} \quad (\text{Eq. 9-4B})$$

$$\text{For weak bases: } pH = pK_b + \log \frac{[B]}{[BH^+]} \quad (\text{Eq. 9-4C})$$

Because uncharged molecules traverse membranes more rapidly, it is understood that weak acids cross membranes more rapidly in an acidic environment, and weak bases move more rapidly in a basic environment. When the pH equals the pK_a , half of the xenobiotic is charged, and half is uncharged. An acid with a low pK_a is a strong acid, and a base with a low pK_a is a weak base. For an acid, a pH less than the pK_a favors the protonated or uncharged species facilitating membrane diffusion, and for a base, a pH greater than the pK_a achieves the same result. [Table 9–1](#) lists the pH of selected body fluids, and [Fig. 9–3](#) illustrates the extent of charged versus uncharged xenobiotic at different pH and pK_a and pK_b values.

TABLE 1 9–1. pH of Selected Body Fluids

Fluids	pH
Cerebrospinal	7.3
Gastric secretions	1–3
Large intestinal secretions	8
Ophthalmic (tears)	7–8
Plasma	7.4
Stool: Infants and children	7.2–12
Saliva	6.4–7.2
Small intestinal secretions: Duodenum	5–6
Small intestinal secretions: Ileum	8
Urine	4–8
Vaginal secretions	3.8–4.5

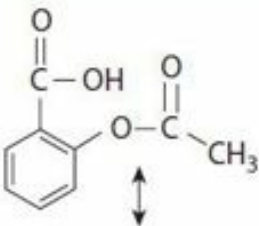

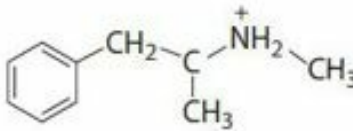

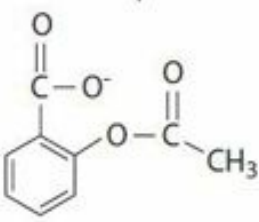

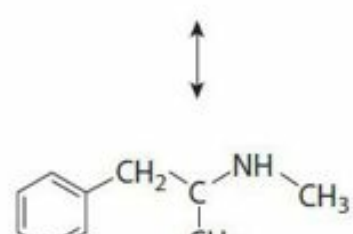

pH	Aspirin ($pK_a = 3.5$)	% Nonionized	Methamphetamine ($pK_a = 10$)	% Nonionized

FIGURE 9–3. Effect of pH on the ionization of aspirin ($pK_a = 3.5$) and methamphetamine ($pK_a = 10$).

Lipid solubility and ionization each have a distinct influence on absorption. **Figure 9–4** demonstrates these characteristics for three different xenobiotics. Although the three xenobiotics have similar pK_a and pK_b values, their different partition constants result in different degrees of absorption from the stomach.

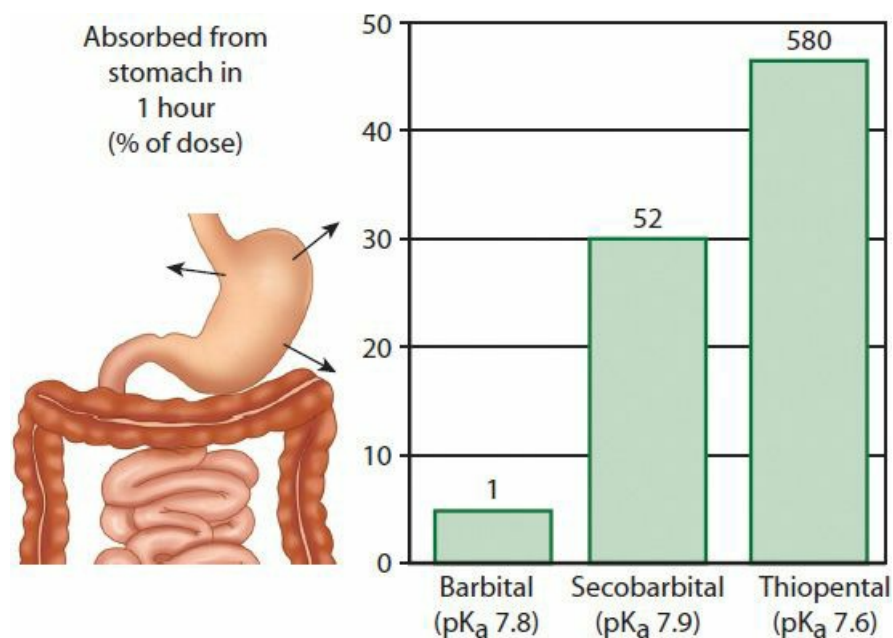

FIGURE 9-4. Influence of increasing lipid solubility on the amount of xenobiotic absorbed from the stomach for three xenobiotics with similar pK_a values. The number above each column is the oil/water equilibrium partition coefficient. (Reprinted with permission from Brody T: Absorption, distribution, metabolism, and elimination. In: Brody TM, Larner J, Minneman KP, Neu HP, eds: Human Pharmacology: Molecular to Clinical, 2nd ed. St. Louis, Mosby, 1994, p 50.)

Specialized transport mechanisms are either adenosine triphosphate (ATP) dependent to transport xenobiotics against a concentration gradient (ie, active transport) or ATP independent and lack the ability to transport against a concentration gradient (ie, facilitated transport). These transport mechanisms are of importance in numerous parts of the body, including the intestines, liver, lungs, kidneys, and biliary system. These same principles apply to a small number of lipid-insoluble molecules that resemble essential endogenous molecules.^{28,64} For example, 5-fluorouracil resembles pyrimidine and is transported by the same system, and thallium and lead are actively absorbed by the endogenous transport mechanisms that absorb and transport potassium and calcium, respectively. Filtration is generally considered to be of limited importance in the absorption of most xenobiotics but is substantially more important with regard to renal and biliary elimination. Endocytosis, which describes the encircling of a xenobiotic by a cellular membrane, is responsible for the absorption of large macromolecules such as the oral Sabin polio vaccine.⁶⁴

Gastrointestinal (GI) absorption is affected by xenobiotic-related characteristics such as dosage form, degree of ionization, partition constant, and patient factors (eg, GI blood flow; GI motility; and the presence or absence of food, ethanol, or other interfering substances such as calcium) (Fig. 9-5).

FIGURE 9-5. Determinants of absorption.

The formulation of a xenobiotic is extremely important in predicting GI absorption. Disintegration and dissolution must precede absorption. Disintegration is usually much more rapid than dissolution except for modified-release products. Modified release is a broad term that encompasses products that are delayed-release and extended-release formulations.

These modified-release formulations are designed to release the xenobiotic over a prolonged period of time to simulate the blood concentrations achieved with the use of a constant IV infusion. By definition, extended-release formulations decrease the frequency of drug administration by at least 50% compared with immediate-release formulations, and they include controlled-release, sustained-release, and prolonged-release formulations. These formulations minimize blood concentration fluctuations, reduce peak-related side effects, reduce dosing frequency, and improve patient compliance. A variety of products use different pharmaceutical strategies, including dissolution control (encapsulation or matrix; Feosol), diffusion control (membrane or matrix; Plendil ER), erosion (Sinemet CR), osmotic pump systems (Procardia XL, Glucotrol XL), and ion exchange resins (MS Contin suspension). Overdoses with modified-release formulations often result in a prolonged absorption phase, a delay to peak concentrations, and a prolonged duration of effect.⁷ Some delayed-release preparations are enteric coated and specifically designed to bypass the stomach and to release drug in the small intestine. Other delayed-release formulations (eg, Verelan PM) are designed to release the drug later but not specifically designed to bypass release in the stomach. Enteric-coated (acetylsalicylic acid {ASA}, divalproex sodium) formulations resist disintegration and delay the time to onset of effect.⁶ Dissolution is affected by ionization, solubility, and the partition coefficient. In the overdose setting, the formation of poorly soluble or adherent masses such as concretions of foreign material termed bezoars significantly delay the time to onset of toxicity (Table 9–2).^{4,11,29,30,60}

TABLE 9–2. Xenobiotics That Form Concretions or Bezoars, Delay Gastric Emptying, or Result in Pylorospasm

Anticholinergics	Meprobamate
Barbiturates	Methaqualone
Bromides	Opioids
Enteric-coated tablets	Phenytoin
Glutethimide	Salicylates
Iron	Verapamil

Most ingested xenobiotics are primarily absorbed in the small intestine as a result of the large surface area and extensive blood flow of the small intestines.⁵⁹ Critically ill patients who are hypotensive, have a reduced cardiac output, or are receiving vasopressors such as norepinephrine have a decreased perfusion of vital organs, including the GI tract, kidneys, and liver.³ Not only is absorption delayed, but elimination is also diminished.⁵⁷ Total GI transit time can be from 0.4 to 5 days, and small intestinal transit time is usually 3 to 4 hours. Extremely short GI transit times reduce absorption. This change in transit time is the unproven rationale for use of whole-bowel irrigation (WBI). Delays in emptying of the stomach impair absorption as a result of the delay in delivery to the small intestine. Delays in gastric emptying occur as a result of the presence of food, especially fatty meals; agents with anticholinergic, opioid, or antiserotonergic properties; ethanol; and any xenobiotic that results in pylorospasm (salicylates, iron).

Bioavailability is a measure of the amount of xenobiotic that reaches the systemic circulation unchanged (Equation 9–5).³⁸ The fractional absorption (F) of a xenobiotic is defined by the area under the plasma drug concentration versus time curve (AUC) of the designated route of absorption compared with the AUC of the IV route. The AUC for each route represents the amount absorbed.

$$F = \frac{(\text{AUC})_{\text{route under study}}}{(\text{AUC})_{\text{IV}}} \quad (\text{Eq. 9-5})$$

Gastric emptying and activated charcoal are used to decrease the bioavailability of ingested xenobiotics. The oral administration of certain chelators (deferoxamine, D-penicillamine) actually enhances the bioavailability of the complexed xenobiotic. The net effect of some chelators, such as succimer, is a reduction in body burden via enhanced urinary elimination even though absorption is enhanced.³¹

Presystemic metabolism may decrease or increase the bioavailability of a xenobiotic or a metabolite.⁵³ The GI tract contains microbial organisms that can metabolize or degrade xenobiotics such as digoxin and oral contraceptives and enzymes, such as peptidases, that metabolize insulin.⁵⁴ However, in rare cases, GI hydrolysis can convert a xenobiotic into a toxic metabolite, as occurs when amygdalin is enzymatically hydrolyzed to produce cyanide, a metabolic step that does not occur when amygdalin is administered intravenously.²⁷ Xenobiotic-metabolizing enzymes and influx and efflux transporters such as organic anion transporting polypeptides (OATP) and P-glycoprotein (P-gp), respectively, may also affect bioavailability. Xenobiotic-metabolizing enzymes are found in the lumen of the small intestine and can substantially decrease the absorption of a xenobiotic.^{44,73} Some of the xenobiotic that enters the cell can then be removed by the P-gp transporter from the cell and returned to the GI lumen and reexposed to the metabolizing enzymes.^{44,73} Venous drainage from the stomach and intestines delivers orally (and intraperitoneally) administered xenobiotics to the liver via the portal

vein and avoids direct delivery to the systemic circulation. This venous drainage allows hepatic metabolism to occur before the xenobiotic reaches the blood, and as previously mentioned, is referred to as the first-pass effect.^{2,76} The hepatic extraction ratio is the percentage of xenobiotic metabolized in one pass of blood through the liver.⁴⁷ Xenobiotics that undergo significant first-pass metabolism (eg, propranolol, verapamil) are used at much lower IV doses than oral doses. Some drugs, such as lidocaine and nitroglycerin, are not administered by the oral route because of significant first-pass effect.⁴ Instead, sublingual, transcutaneous (topical), and rectal administration of drugs are used to bypass the portal circulation and avoid first-pass metabolism.

In the overdose setting, presystemic metabolism may be saturated, leading to an increased bioavailability of xenobiotics such as cyclic antidepressants, phenothiazines, opioids, and many β -adrenergic antagonists.⁵⁶ Hepatic metabolism usually transforms the xenobiotic into a less active metabolite but occasionally results in the formation of a more toxic xenobiotic such as occurs with the transformation of parathion to paraoxon.⁵¹ Biliary excretion into the small intestine usually occurs for these transformed xenobiotics of molecular weights greater than 350 Da and may result in a xenobiotic appearing in the feces even though it had not been administered orally.^{34,54,67} Hepatic conjugated metabolites such as glucuronides may be hydrolyzed in the intestines to the parent form or to another active metabolite that can be reabsorbed by the enterohepatic circulation.^{41,49,52,54} The enterohepatic circulation may be responsible for what is termed a double-peak phenomenon after the administration of certain xenobiotics.⁶⁴ The double-peak phenomenon is characterized as a serum concentration that decreases and then increases again as xenobiotic is reabsorbed from the GI tract. Other causes include variability in stomach emptying, presence of food, or failure of a tablet dosage form.⁶⁴

DISTRIBUTION

After the xenobiotic reaches the systemic circulation, it is available for transport to peripheral tissue compartments and to the liver and kidney for elimination. Both the rate and extent of distribution depend on many of the same principles discussed with regard to diffusion. Additional factors include affinity of the xenobiotic for plasma (plasma protein binding) and tissue proteins, acid–base status of the patient (which affects ionization), drug transporters, and physiologic barriers to distribution (blood–brain barrier, placental transfer, blood–testis barrier).^{23,35,58} Blood flow, the percentage of free xenobiotic in the plasma, the activity of transporters account for the initial phase of distribution, and xenobiotic affinities determine the final distribution pattern. Whereas the adrenal glands, kidneys, liver, heart, and brain receive from 55 to 550 mL/min/100 g of tissue of blood flow, the skin, muscle, connective tissue, and fat receive 1 to 5 mL/min/100 g of tissue of blood flow.⁶² Hypoperfusion of the various organs in the critically ill and injured affects absorption, distribution, and elimination.⁷⁴

ATP-binding cassette (ABC) transporters are active ATP-dependent transmembrane protein carriers of which P-gp was the initial example discovered.⁹ Approximately 50 ABC transporters exist, and they are divided into subfamilies based on their similarities. Several members of the ABC superfamily, including P-gp, are under extensive investigation because of their role in controlling xenobiotic entry into, distribution in, and elimination from the body as well as their contributions to xenobiotic interactions.^{21,32,73} The discovery of P-gp resulted from an investigation into why certain tumors exhibit multidrug resistance to many antineoplastics. P-gp (ABCB1) as well as ABCC and ABCG2 are known to be efflux transporters located in the intestines, renal proximal tubules, hepatic bile canaliculi, placenta, and blood–brain barrier and are responsible for the intra- to extracellular transport of various xenobiotics.¹⁶ First-generation transport inhibitors such as amiodarone, ketoconazole, quinidine, and verapamil are responsible for increasing body concentrations of P-gp substrates such as digoxin, the protease inhibitors, vinca alkaloids, and paclitaxel. St. John's wort is a transport inducer, and it lowers serum concentrations of these same xenobiotics. Second- and third-generation xenobiotics that will affect transport with a higher affinity and specificity are in development.^{18,65} Many of the same xenobiotics that affect cytochrome P450 CYP3A4 also affect P-gp (Appendix Chap. 13: Cytochrome P450 Substrates Inhibitors and Inducers).

The organic anion transporting polypeptides (OATPs) are another group of transporters found in the liver, kidneys, intestines, brain, and placenta that affect the absorption, distribution, and elimination of many xenobiotics and contribute to xenobiotic interactions. They include the organic anion transporters (OATs) and the organic cation transporters (OCTs).¹⁸ For example, probenecid increases the serum concentrations of penicillin by inhibiting the OAT responsible for the active secretion of penicillin by the renal tubular cells, and cimetidine inhibits the OCT responsible for the renal elimination of procainamide and metformin. A variety of OAT inhibitors are being investigated to decrease the hepatic uptake of amatoxins¹⁸ (Chap. 120).

Volume of distribution (V_d) is the proportionality term used to relate the dose of the xenobiotic that the individual receives with the resultant plasma concentration. V_d is an apparent or theoretical volume into which a xenobiotic distributes. It is a measure of how much xenobiotic is located inside versus outside of the plasma compartment after administration of a xenobiotic. Because only the plasma compartment is routinely assayed, the amount that remains in the plasma can be used to calculate the movement out of the blood. In a 70-kg man, the total body water (TBW) is 60% of total

body weight, or 42 L, with two-thirds (28 L) of the fluid accounted for by intracellular fluid. Of the 14 L of extracellular fluid, 8 L is considered interstitial or between the cells; 3 L, or 0.04 L/kg, is plasma; and 6 L, or 0.08 L/kg, is blood. If 42 g of a xenobiotic is administered and remains in the plasma compartment ($V_d = 0.04$ L/kg), the concentration would be 15 g/L. If the distribution of the 42 g of xenobiotic approximated TBW (methanol; 0.6 L/kg), the concentration would be 1 g/L (usually reported as 100 mg/dL). These calculations can be performed by using Equation 9–6, where S equals the percent pure drug if a salt form is used.

$$Vd = \frac{S \times F \times \text{Dose (mg)}}{C_0}$$

(Eq. 9-6)

Experimental determination of V_d involves administering an IV dose of the xenobiotic and extrapolating the plasma concentration time curve back to time zero (C_0). If the determination takes place after steady state has been achieved, the volume of distribution is then referred to as the $V_{d_{ss}}$. For many xenobiotics, the V_d is known and readily available in the literature (Table 9–3). When the V_d and the dose ingested are known, a maximum predicted plasma concentration can be calculated after assuming all of the xenobiotic is absorbed and no elimination occurred. This assumption usually overestimates the plasma concentration. Distribution is complex, and differential affinities for various storage sites in the body, such as plasma proteins, liver, kidney, fat, and bone, determine where a xenobiotic ultimately resides.

TABLE 9–3. Pharmacokinetic Characteristics of Xenobiotics Associated with Significant Morbidity and Mortality

	<i>V_d</i> (L/kg)	<i>Protein Binding</i> (%)	<i>Renal Elimination</i> (% Unchanged)	<i>Hepatic Metabolism</i> (CYP)	<i>Active Metabolite</i>	<i>Enterohepatic</i>
Analgesics						
Acetaminophen (APAP)	0.8–1.0	5–20	2	95% 5–10% (2E1)	<i>N</i> -acetyl- <i>p</i> -benzoquinonimine Salicylic acid	27%–42% excreted in bile
Aspirin	0.15–0.20	50–80 (salicylic acid) saturable	10 (pH dependent)	Majority		None
Methadone	3.59	71–87	5–10	Majority (3A4, 2D6) <i>n</i> -Demethylation	None?	Yes
Morphine	3–4	35	<10		15% Morphine 6-glucuronide, 55% morphine 3-glucuronide	Yes
Oxycodone	2.6	45	19	>64% (3A4, 2D6) Noroxycodone	Oxymorphone	No?
Antidepressants						
Amitriptyline	8.3 ± 2	96	5	Yes (2C9)	Nortriptyline (2D6)	Yes
Bupropion	18.6	84	0	Yes (2B6)	Hydroxybupropion	No
Citalopram	12	80	0	Yes (3A4, 2C19)	Desmethylcitalopram	Yes
Desipramine	33–42	92	0.3–2.6	Yes (2D6)	None	Yes
Doxepin	20 ± 8	—	0	Yes	Desmethyldoxepin	Yes
Imipramine	15 ± 6	85	0–1.7	Yes (2D6)	Desipramine	Yes
Lithium	0.79	None	89–98	None	None	None
Cardiovascular						
Digoxin	5.1–7.4	20–25	50–80		Minor amount	Yes
Diltiazem	5.3	70–80	1–3	90% (3A)	Yes, many	No
Nifedipine	0.8–1.4	9–98	7	98% (3A4)	No	No
Propranolol	3.6	93	<0.5	>95% (2C19, 2D6)	No	No
Verapamil	4.7	83–92	3–4%	97% (3A4, 1A2, 2C9)	Norverapamil	No
Stimulants and Drugs of Abuse						
Amphetamine	6.11 (in drug dependent) 3.5–4.6 (in naive)	16	45 (pH dependent)	50%	<i>p</i> -Hydroxynorephedrine 0.3%; <i>p</i> -hydroxyamphetamine 2%–4%	No
Cocaine	1.96–2.7	8.7	9.5–20 (pH dependent)	5–10%	Norcocaine; (?) others	No
Heroin	25	40	Minor	Yes	Acetylmorphine, morphine	No
Methamphetamine	3.2–3.7	pH dependent			Amphetamine 4%–7%; <i>p</i> -hydroxymethamphetamine 15%	No
Sedative-Hypnotics						
Alprazolam	1–2	80	100%	None	None	No
Chloral hydrate	0.75	70–80	Minor	Alcohol dehydrogenase	Trichloroethanol	No
Phenobarbital	0.88	40–50	20–50 (pH dependent)	Yes (2C9, 2C19)	None	No
Quetiapine	10	83	0	Yes (3A4)	None	Yes
Alcohols						
Ethanol	0.5–0.6	None	Very little	95% Alcohol dehydrogenase	Acetaldehyde	No
Ethylene glycol	0.6–0.8	None	20	Alcohol dehydrogenase	Oxalic and glycolic acids	No
Methanol	0.6–0.7	None	3–5	95% alcohol dehydrogenase	Formic acid	No
Miscellaneous						
Cyanide	0.4	60	0		Thiocyanate	None
Theophylline	0.5	50–60	7	90% (1A2, 2E1 > 3A4)	1,3-Dimethylxanthine; caffeine (in neonates)	
Organic Phosphorus Compounds						
Malathion	NA	None		Microsomal enzymes	Malaoxon	No
Chlorpyrifos	NA	None		Yes	3,5,6-Trichloro-2 pyridinol	No
Rodenticides						
Brodifacoum	0.985 (rats)	None		Yes		Yes
Strychnine	13	None	10–20 in 24 hr	Yes		No

For the purposes of determining the utility of extracorporeal removal of a xenobiotic, a low V_d is often considered to be less than 1 L/kg. For some xenobiotics, such as digoxin ($V_d = 7$ L/kg) and the cyclic antidepressants ($V_d = 10\text{--}15$ L/kg), the V_d is much larger than the actual volume of the body. A large V_d indicates that the xenobiotic resides outside of the plasma compartment, but again, it does not describe the site of distribution.

The site of accumulation of a xenobiotic may or may not be a site of action or toxicity. If the site of accumulation is not a site of toxicity, then the storage depot may be relatively inactive, and the accumulation at that site may be theoretically protective to the animal or person.⁵⁸ Selective accumulation of xenobiotics occurs in certain areas of the body because of affinity for certain tissue-binding proteins. For example, the kidney contains metallothionein, which has a high affinity for metals such as cadmium, lead, and mercury.²³ The retina contains the pigment melanin, which binds and accumulates chlorpromazine, thioridazine, and chloroquine.²³ Other examples of xenobiotics accumulating at primary sites of toxicity are carbon monoxide binding to hemoglobin and myoglobin and paraquat distributing to type II alveolar cells in the lungs.⁵⁵ Dichlorodiphenyltrichloroethane (DDT), chlordane, and polychlorinated biphenyls are stored in fat and can be mobilized if malnutrition develops.⁷⁷ Lead sequestered in bone³³ is not immediately toxic, but mobilization of bone through an increase in osteoclast activity⁵⁸ (hyperparathyroidism, pregnancy, immobilization) may free lead for distribution to sites of toxicity in the central nervous system (CNS) or blood.

Several plasma proteins bind xenobiotics and act as carriers and storage depots. The percentage of protein binding varies among xenobiotics, as do their affinities and potential for reversibility. After it is bound to plasma protein, a xenobiotic with high binding affinity will remain largely confined to the plasma until elimination occurs. However, dissociation and reassociation may occur if another carrier is available with a higher binding affinity. Most plasma measurements of xenobiotic concentrations reflect total xenobiotic (bound plus unbound). Only the unbound xenobiotic is free to diffuse through membranes for distribution or for elimination. Albumin binds primarily to weakly acidic, poorly water-soluble xenobiotics, which include salicylates, phenytoin, and warfarin, as well as endogenous substances, including free fatty acids, cortisone, aldosterone, thyroxine, and unconjugated bilirubin.⁶² α_1 -Acid glyco-protein usually binds basic xenobiotics, including lidocaine, imipramine, and propranolol.⁶² Transferrin, a β_1 -globulin, transports iron, and ceruloplasmin carries copper.

Phenytoin is an example of a xenobiotic whose effects are significantly influenced by changes in concentration of plasma albumin because only free phenytoin is active. When albumin concentrations are in the normal range, approximately 90% of phenytoin is bound to albumin. As the albumin concentration decreases, more phenytoin is free for distribution, and a greater clinical response to the same serum phenytoin concentration is often observed. The free plasma phenytoin concentration can be calculated based on the albumin concentration. This achieves an appropriate interpretation (adjusted) of total phenytoin within the conventional therapeutic range of 10 to 20 mg/L of free plus bound phenytoin (Equation 9-7).

$$\text{Adjusted phenytoin concentration} = \frac{\text{Actual phenytoin concentration}}{(0.25 \times [\text{albumin}] + 0.1)} \quad (\text{Eq. 9-7})$$

The clinical implications are that a malnourished patient with an albumin of 2 g/dL receiving phenytoin can manifest toxicity with a plasma phenytoin concentration of 14 mg/L. This measurement is total phenytoin (bound + unbound). Because the patient has a reduced albumin concentration, this actually represents a substantially higher proportion and absolute amount of active unbound phenytoin. Substitution into the above equation of 14 mg/L for actual plasma phenytoin concentration and 2 g/dL for albumin gives an adjusted plasma phenytoin concentration of 23.3 mg/L (therapeutic range, 10–20 mg/L).

Although drug interactions are often attributed to the displacement of xenobiotics from plasma protein binding, concurrent metabolic interactions are usually more consequential. Displacement transiently increases the amount of unbound, active drug. This may result in an immediate increase in drug effect. This is followed by enhanced distribution and elimination of unbound drug. Gradually, the unbound plasma concentration returns to predisplacement concentrations.⁵⁹

Saturation of plasma proteins may occur in the therapeutic range for a drug such as valproic acid. Acute saturation of plasma protein binding after an overdose often leads to consequential adverse effects. Saturation of plasma protein binding with salicylates and iron after overdose increase distribution to the CNS (salicylates) or to the liver, heart, and other tissues (iron), increasing toxicity.

Specific therapeutic maneuvers in the overdose setting are designed to alter xenobiotic distribution by inactivating or enhancing elimination to limit toxicity. These therapeutic maneuvers include manipulation of serum or urine pH (salicylates), the use of chelators (lead), and the use of antibodies or antibody fragments (digoxin).

The V_d permits predictions about plasma concentrations and assists in defining whether an extracorporeal method of removal is beneficial for a particular toxin. If the V_d is large (>1 L/kg), it is unlikely that hemodialysis, hemoperfusion, or

exchange transfusion would be effective because most of the xenobiotic is outside of the plasma compartment. Plasma protein binding also influences this decision. If the xenobiotic is more tightly bound to plasma proteins than to activated charcoal, then hemoperfusion is unlikely to be beneficial even if the V_d of the xenobiotic is small. In addition, high plasma protein binding limits the effectiveness of hemodialysis because only unbound xenobiotic will freely cross the dialysis membrane. Exchange transfusion can be effective for a xenobiotic with a small V_d and substantial plasma protein binding because both bound and free xenobiotic are removed simultaneously.

ELIMINATION

Removal of a parent xenobiotic from the body (elimination) begins as soon as the xenobiotic is delivered to clearance organs such as the liver, kidneys, and lungs. Elimination includes biotransformation and excretion. Elimination begins immediately but may not be the predominant kinetic process until absorption and distribution are substantially completed. The functional integrity of the cardiovascular, pulmonary, renal, and hepatic systems are major determinants of the efficiency of xenobiotic removal and of therapeutically administered antidotes. The xenobiotics themselves may cause kidney or liver (eg, APAP) failure, subsequently compromising their own elimination. Other factors that influence elimination include older age (enzyme maturation), competition or inhibition of elimination processes by interacting xenobiotics, saturation of enzymatic processes, gender, pharmacogenetics and pharmacogenomics, obesity, and the physicochemical properties of the xenobiotic.⁴⁶

Elimination can be accomplished by biotransformation to one or more metabolites or by excretion from the body of unchanged xenobiotic. Excretion may occur via the kidneys, lungs, GI tract, and body secretions (sweat, tears, milk). Because of their water solubility, hydrophilic (polar) or charged xenobiotics and their metabolites are generally excreted via the kidney. The majority of xenobiotic metabolism occurs in the liver, but it also occurs in the blood, skin, GI tract, placenta, or kidneys. Lipophilic (uncharged or nonpolar) xenobiotics are usually metabolized in the liver to hydrophilic metabolites, which are then excreted by the kidneys.^{24,51} These metabolites are generally inactive, but if active, they may contribute to toxicity. Examples of active metabolites include nortriptyline (derived from amitriptyline), N-acetylprocainamide (derived from procainamide) and normeperidine (derived from meperidine).

Metabolic reactions catalyzed by enzymes, categorized as either phase I or phase II, may result in pharmacologically active metabolites; frequently, the latter have different toxicities than the parent compounds. Phase I (asynthetic), or preparative metabolism, which may or may not precede phase II, is responsible for introducing polar groups onto nonpolar xenobiotics by oxidation (hydroxylation, dealkylation, deamination), reduction (alcohol dehydrogenase, azo reduction), and hydrolysis (ester hydrolysis).^{22,49} Phase II, or synthetic, reactions conjugate the polar group with a glucuronide, sulfate, acetate, methyl or glutathione or amino acids such as glycine, taurine, and glutamic acid, creating more polar metabolites.^{14,22,49}

Comparatively, phase II reactions produce a much larger increase in hydrophilicity than phase I reactions. The enzymes involved in these reactions have low substrate specificity, and those in the liver are usually localized to either the endoplasmic reticulum (microsomes) or the soluble fraction of the cytoplasm (cytosol).⁴⁹ The location of the enzymes becomes important if they form reactive metabolites, which then concentrate at the site of metabolism and cause toxicity. For example, APAP causes centrilobular necrosis because the CYP2E1 enzymes, which form N-acetyl-p-benzoquinoneimine (NAPQI), the toxic metabolite, are located in their highest concentration in that zone of the liver.

The enzymes that metabolize the largest variety of xenobiotics are heme-containing proteins referred to as CYP monooxygenase enzymes.^{28,49} This group of enzymes, formerly called the mixed function oxidase system, is found in abundance in the microsomal endoplasmic reticulum of the liver. These cytochrome P450 metabolizing enzymes (CYPs) primarily catalyze the oxidation of xenobiotics. Cytochrome P450 in a reduced state (Fe^{2+}) binds carbon monoxide. Its discovery and initial name resulted from spectral identification of the colored CO-bound cytochrome P450, which absorbs light maximally at 450 nm. The cytochrome P450 system is composed of many enzymes grouped according to their respective gene families and subfamilies, of which approximately 57 of these functional human genes have been sequenced. Members of a gene family have more than 40% similarity of their amino acid sequencing, and subfamilies have more than 55% similarity. For example, the CYP2D6*1a gene encodes wild-type protein (enzyme) CYP2D6, where 2 represents the family, D the subfamily and 6 the individual gene, and *1a the mutant allele; CYP2D6.1 represents the most common or wild-type allele.

Toxicity may result from induction or inhibition of CYP enzymes by another xenobiotic, resulting in a consequential drug interaction (Chap. 13). Many of these interactions are predictable based on the known xenobiotic affinities and their capability to induce or inhibit the P450 system.^{12,42,49,50,66} However, polymorphism (individual genetic expression of enzymes),¹ stereoisomer variability⁷⁵ (enantiomers with different potencies and isoenzyme affinities), and the capability to metabolize a xenobiotic by alternate pathways contribute to unexpected metabolic outcomes. The pharmaceutical industry is now exploiting the concept of chiral switching (marketing a single enantiomer instead of the racemic mixture) to alter efficacy or side effect profiles. Enantiomers are named either according to the direction in which they rotate polarized light

(l or – for levorotatory, and d or + for dextrorotatory) or according to the absolute spatial orientation of the groups at the chiral center (S or R). Chiral means “hand” in Greek, and the latter designations refer to either sinister (left-handed) or rectus (right-handed). There is no direct correlation between levorotatory or dextrorotatory and S and R, which indicates the direction polarized light is rotated by a solution of the xenobiotic.⁷⁰

The liver reduces the oral bioavailability of xenobiotics with high extraction ratios. The bioavailabilities of xenobiotics with high extraction ratios are greatly affected by enzyme induction and enzyme inhibition; the reverse is true for xenobiotics with a low extraction ratio. After the xenobiotic is in the blood, the hepatic elimination is affected by blood flow to the liver, the intrinsic hepatic metabolism, and plasma protein binding. If the hepatic metabolism of a xenobiotic is very high, then the only limit to hepatic clearance is blood flow to the liver, and not protein binding. However, if the intrinsic hepatic metabolism for a xenobiotic is low, then blood flow to the liver is not consequential. Plasma protein binding becomes important because only unbound xenobiotics can be cleared by the liver. Because enzyme inhibition and induction greatly affect intrinsic hepatic metabolism, these factors are also important.

Excretion is primarily accomplished by the kidneys, with biliary, pulmonary, and body fluid secretions contributing to lesser degrees. Urinary excretion occurs through glomerular filtration, tubular secretion, and passive tubular reabsorption. The glomerulus filters unbound xenobiotics of a particular size and shape in a manner that is not saturable (but is subject to renal blood flow and perfusion). Passive tubular reabsorption accounts for the reabsorption of uncharged, lipid-soluble xenobiotics and is therefore influenced by the pH of the urine and the pK_a or pK_b of the xenobiotic. The principles of diffusion discussed earlier permit, for example, the ion trapping of salicylate ($pK_a = 3.5$) in the urine through urinary alkalization. Tubular secretion is an active process carried out by drug transporters (OATs, OCTs) and subject to saturation and drug interactions (Table 9–4).

TABLE 9–4. Xenobiotics Secreted by Renal Tubules

<i>Organic Anion Transport</i>	<i>Organic Cation Transport</i>
Acetazolamide	Acetylcholine
Bile salts	Amiodarone
Cephalosporins	Atropine
Indomethacin	Cimetidine
Hydrochlorothiazide	Digoxin
Furosemide	Diltiazem
Methotrexate	Dopamine
Penicillin G	Epinephrine
Probenecid	Morphine
Prostaglandins	Neostigmine
Salicylates	Procainamide
	Quinidine
	Quinine
	Triamterene
	Trimethoprim
	Verapamil

The effects of obesity on elimination are being studied. Obesity is the accumulation of adipose tissue far in excess of that which is considered normal for a person’s age and gender. The National Institutes of Health defines obesity as a body mass index (BMI) greater than 30 and overweight as a BMI between 25 and 29.9. The BMI is calculated by dividing a person’s weight in kilograms by the individual’s height in meters squared (m^2). By this criterion, about one-third of the adult US population is obese. Obesity poses problems in determining the correct loading dose and maintenance dose for therapeutic xenobiotics and for the estimation of serum concentrations and elimination times in the overdose setting.^{10,26,39,48} A number of formulas have been proposed to classify body size in addition to BMI, but none has been tested adequately in the obese population. Obese patients have not only an increase in adipose tissue but also an increase in lean body mass of 20% to 55%, which results in the alteration of the distribution of both lipophilic and hydrophilic xenobiotics. In general, the absorption of xenobiotics in obese patients does not appear to be affected, but distribution is affected. The effect of obesity on hepatic metabolism requires additional study, although some studies suggest a nonlinear increase in clearance. The glomerular filtration rate increases in obesity. For example, although aminoglycosides are hydrophilic, because of an increase in fat free mass in obese patients, a dosing weight correction of 40% is used to calculate both the loading dose and the maintenance dose ($\text{Dosing body weight} = 0.4 \times \{\text{Actual body weight} - \text{Ideal body weight}\} + \text{Ideal body weight}$). Preliminary studies with propofol, a very lipophilic drug, suggest that induction and maintenance doses correlate better with actual body weight. These equations are found in Table 9–5. One recent evaluation suggests using 40% of actual body weight instead of ideal body weight in the Cockcroft-Gault formula to estimate kidney

function in the obese.

TABLE 9–5. Equations for Determining Body Size

$\text{BMI} = \frac{\text{Weight (kg)}}{\text{Height (m}^2\text{)}}$
$\text{BSA (m}^2\text{)} = \frac{\sqrt{\text{Height (cm)} \times \text{Weight (kg)}}}{\sqrt{3600}}$
IBW: Males (kg) = 50 + 2.3 (Height > 60 in)
IBW: Females (kg) = 45.5 + 2.3 (Height > 60 in)
$\text{LBW}_{2005} \text{ : Males (kg)} = \frac{9270 \times \text{Weight (kg)}}{6680 + [(216 \times \text{BMI (kg/m}^2\text{)})]}$
$\text{LBW}_{2005} \text{ : Females (kg)} = \frac{9270 \times \text{Weight (kg)}}{8780 + [(244 \times \text{BMI (kg/m}^2\text{)})]}$

BMI = body mass index; BSA = body surface area; IBW = ideal body weight; LBW = lean body weight.

CLASSICAL VERSUS PHYSIOLOGIC COMPARTMENT TOXICOKINETICS

Models exist to study and describe the movement of xenobiotics in the body with mathematical equations. Traditional compartmental models (one or two compartments) are data based and assume that changes in plasma concentrations represent proportional changes in tissue concentrations (Fig. 9–6).⁴⁷ Advances in computer technology facilitate the use of the classic concepts developed in the late 1930s.⁶⁹ Physiologic models consider the unique movement characteristics of xenobiotics based on known or theoretical biologic processes. This allows the prediction of tissue concentrations while incorporating the effects of changing physiologic parameters and affording better extrapolation from laboratory animals.⁷⁹ Unfortunately, physiologic modeling is still in its infancy, and the mathematical modeling it entails is often very complex.¹⁹ The commonest mathematical equations used are based on traditional compartmental modeling.

Model 1. One-compartment open model, IV injection.

Model 2. One-compartment open model with first-order absorption.

Model 3. Two-compartment open model, IV injection.

Model 4. Two-compartment open model with first-order absorption.

FIGURE 9–6. Various classical compartmental models. 1, plasma or central compartment; 2 = tissue compartment; IV,

intravenous; k_a = absorption rate constant; k_e = pharmacokinetic elimination rate constants; k_{12} = rate constant into tissue from plasma; k_{21} = rate constant into plasma from tissue.

The one-compartment model is the simplest approach for analytic purposes and is applied to xenobiotics that enter and rapidly distribute throughout the body. This model assumes that changes in plasma concentrations will result in and reflect proportional changes in tissue concentrations. Many xenobiotics, such as digoxin, lithium, and lidocaine, do not instantaneously equilibrate with the tissues and are better described by a two-compartment model. In the two-compartment or more than two-compartment model, a xenobiotic is distributed instantaneously to highly perfused tissues (central compartment) and then is secondarily, and more slowly, distributed to a peripheral compartment. Elimination is assumed to take place from the central compartment.

If the rate of a reaction is directly proportional to the concentration of xenobiotic, it is termed first order or linear. Processes that are capacity limited or saturable are termed nonlinear (not proportional to the concentration of xenobiotic) and are described by the Michaelis-Menten equation, which is derived from enzyme kinetics. Calculus is used to derive the first-order equation.⁷⁹ Rate is directly proportional to concentration of xenobiotic, as in Equation 9–8.

$$\text{Rate} \propto \text{concentration (C)} \quad (\text{Eq. 9-8})$$

An infinitesimal change in concentration of a xenobiotic (dC) with respect to an infinitesimal change in time (dt) is directly proportional to the concentration (C) of the xenobiotic as in Equation 9–9:

$$\frac{dC}{dt} \propto C \quad (\text{Eq. 9-9})$$

The proportionality constant k is added to the right side of the expression to mathematically allow the introduction of an equality sign. The constant k represents all of the bodily factors, such as metabolism and excretion, which contribute to the determination of concentration (Equation 9–10).

$$\frac{dC}{dt} = kC \quad (\text{Eq. 9-10})$$

Introducing a negative sign to the left-hand side of the equation describes the “decay” or decreasing xenobiotic concentration (Equation 9–11).

$$-\frac{dC}{dt} = kC \quad (\text{Eq. 9-11})$$

This equation is impractical because of the difficulty of measuring infinitesimal changes in C or t . Therefore, the use of calculus allows the integration or summing of all of the changes from one concentration to another beginning at time zero and terminating at time t . This relationship is mathematically represented by the integration sign (\int). The sign \int means to integrate the term from concentration at time zero (C_0) to concentration at a given time t (C_t). \int means the same with respect to time, where $t_0 = \text{zero}$. Before this application, the previous equation is first rearranged (Equation 9–12).

$$\begin{aligned} -\frac{dC}{C} &= k dt \\ \int_{C_0}^{C_t} -\frac{dC}{C} &= k \int_0^t dt \end{aligned} \quad (\text{Eq. 9-12})$$

The integration of dC divided by C is the natural logarithm of C ($\ln C$), and the integration of dt is t (Equation 9–13).

$$-\ln C \Big|_{C_0}^{C_t} = kt \Big|_{t_0}^t \quad (\text{Eq. 9-13})$$

The vertical straight lines proscribe the evaluation of the terms between those two limits. The following series of manipulations is then performed (Equation 9–14A–D).

$$-(\ln C_t - \ln C_0) = k(t - 0) \quad (\text{Eq. 9-14A})$$

$$-\ln C_t + \ln C_0 = kt \quad (\text{Eq. 9-14B})$$

$$-\ln C_t = -\ln C_0 + kt \quad (\text{Eq. 9-14C})$$

$$\begin{array}{ccc} -\ln C_t = & \ln C_0 - & kt \\ \text{Can be} & \text{Constant} & \text{Can be} \\ \text{measured} & & \text{selected} \end{array} \quad (\text{Eq. 9-14D})$$

Equation 9–14D can be recognized as taking the form of an equation of a straight line (Equation 9–15), where the slope is equal to the negative rate constant k and the intercept is C_0 .

$$y = b + mx \quad (\text{Eq. 9-15})$$

Instead of working with natural logarithms, an exponential form (the antilog) of Equation 9–14D may be used (Equation 9–16).

$$C_t = C_0 e^{-kt} \quad (\text{Eq. 9-16})$$

Graphing the \ln (natural logarithm) of the concentration of the xenobiotic at various times for a first-order reaction is a straight line. Equation 9–16 describes the events when only one first-order process occurs. This is appropriate for a one-compartment model (Fig. 9–7).

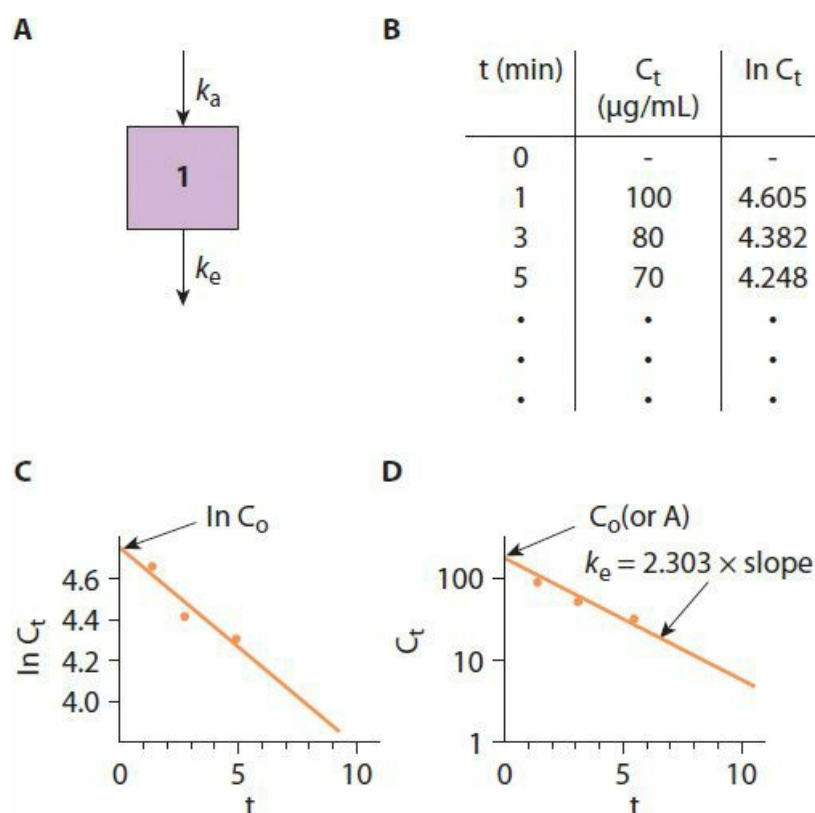

FIGURE 9–7. A one-compartment pharmacokinetic model demonstrating graphical illustration (A), hypothetical dataset (B), linear plot (C), and semilogarithmic plot (D).

In this model, regardless of the concentration of the xenobiotic, the rate (percentage) of decline is constant. The absolute amount of xenobiotic eliminated changes continuously while the percent eliminated remains constant. k is reported in h^{-1} . A k_e of 0.10 h^{-1} means that the xenobiotic is being processed (eliminated) at a rate of 10% per hour. k is often designated as k_e and referred to as the elimination rate constant. The time necessary for the xenobiotic concentration to be reduced by 50% is called the half-life. The half-life is determined by a rearrangement of Equation 9–14D whereby C_2 becomes C at time t_2 and C_1 becomes C at t_1 and by rearrangement giving Equation 9–17:

$$(t_1 - t_2) = \frac{(\ln C_1 - \ln C_2)}{k_e} \quad (\text{Eq. 9-17})$$

Substitution of 2 for C_1 and 1 for C_2 or 100 for C_1 and 50 for C_2 gives Equations 9–18A and 9–18B:

$$t_{1/2} = \frac{(\ln 2 - \ln 1)}{k_e} \quad (\text{Eq. 9-18A})$$

$$t_{1/2} = \frac{0.693}{k_e} \quad (\text{Eq. 9-18B})$$

The use of semilog paper facilitates graphing the first-order equation. If natural logs are used to calculate slope, then $k_e = -\text{slope}$, and if common logs are used to calculate slope, then $k_e = -2.303 \times \text{slope}$ (Fig. 9–7).

The mathematical modeling becomes more complex when more than one first-order process contributes to the overall elimination process. The equation that incorporates two first-order rates is used for a two-compartment model and is Equation 9–19.

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} \quad (\text{Eq. 9-19})$$

Figure 9–8 demonstrates a two-compartment model where α often represents the distribution phase and β is the elimination phase.

FIGURE 9–8. Mathematical and graphical forms of a two-compartment classical pharmacokinetic model. k_a represents the absorption rate constant, k_e represents the elimination rate constant, α represents the distribution phase, and β represents the elimination phase.

The rate of reaction of a saturable process is not linear (ie, not proportional to the concentration of xenobiotic) when saturation occurs (Fig. 9–9). This model is best described by the Michaelis-Menten equation used in enzyme kinetics (Equation 9–20) in which v is the velocity or rate of the enzymatic reaction, C is the concentration of the xenobiotic, V_{\max} is the maximum velocity of the reaction between the enzyme and the xenobiotic at high xenobiotic concentrations, and K_m is the substrate concentration at which the reaction rate is half of the V_{\max} .⁷⁹

FIGURE 9-9. Concentration versus time curve for a xenobiotic showing nonlinear pharmacokinetics where concentrations below 10 mg/mL represent first-order elimination. C, concentration; K_m , affinity constant; v , velocity; V_{max} , maximum velocity.

$$v = \frac{V_{max} \times C}{K_m + C} \quad (\text{Eq. 9-20})$$

Application of this equation to toxicokinetics requires v to become the infinitesimal change in concentration of a xenobiotic (dC) with respect to an infinitesimal change in time (dt) as previously discussed (Equation 9-10). V_{max} and K_m both reflect the influences of diverse biologic processes. The Michaelis-Menten equation then becomes Equation 9-21, in which the negative sign again represents decay:

$$-\frac{dC}{dt} = \frac{V_{max} \times C}{K_m + C} \quad (\text{Eq. 9-21})$$

When the concentration of the xenobiotic is very low ($C \ll K_m$), it can be dropped from the bottom right of the equation because its contribution becomes negligible, and the resultant equation is described as a first-order process (Equation 9-22A and 9-22B). Conceptually, this is understandable because at a very low xenobiotic concentration, the process is not saturated.

$$-\frac{dC}{dt} = \frac{V_{max} \times C}{K_m} \quad (\text{Eq. 9-22A})$$

Because V_{max} divided by K_m is a constant, k , then:

$$-\frac{dC}{dt} = kC \quad (\text{Eq. 9-22B})$$

However, when the concentrations of the xenobiotic are extremely high and exceed the capacity of the system ($C \gg K_m$), the rate becomes fixed at a constant maximal rate regardless of the exact concentration of the xenobiotic, termed a zero-order reaction. [Tables 9-6A and 9-6B](#) compare a first-order reaction with a zero-order reaction. In this particular example, zero order is faster, but if the fraction of xenobiotic eliminated in the first-order example were 0.4, then the amount of xenobiotic in the body would decrease below 100 before the xenobiotic in the zero-order example. It is inappropriate to perform half-life calculations on a xenobiotic displaying zero-order behavior because the metabolic rates are continuously changing. Sometimes the term apparent half-life is used if it is unclear if the xenobiotic is exhibiting zero-order or first-order pharmacokinetics. After an overdose, enzyme saturation is a common occurrence because the capacity of enzyme systems is overwhelmed.

CLEARANCE

Clearance (Cl) is the relationship between the rate of transfer or elimination of a xenobiotic from a reference fluid (usually plasma) to the plasma concentration (Cp) of the xenobiotic and is expressed in units of volume per unit time mL/min (Equation 9–23).^{25,47,61}

$$Cl = \frac{\text{Rate of elimination}}{C_p} \quad (\text{Eq. 9-23})$$

The determination of creatinine clearance is a well-known example of the concept of clearance. Creatinine clearance (Cl_{CR}) is determined by Equation 9–24:

$$Cl_{\text{creatinine}} = \frac{U \times V}{C_p} \quad (\text{Eq. 9-24})$$

in which U is the concentration of creatinine in urine (mg/mL), V is the volume flow of urine (mL/min), Cp is the plasma concentration of creatinine (mg/mL), and the units for clearance are milliliters per minute. A creatinine clearance of 100 mL/min means that 100 mL of plasma is completely cleared of creatinine every minute. Clearance for a particular eliminating organ or for extracorporeal elimination is calculated with Equation 9–25:

$$Cl = Q_b \times (ER) = Q_b \times \frac{(C_{in} - C_{out})}{C_{in}} \quad (\text{Eq. 9-25})$$

Cl = clearance for the eliminating organ or extracorporeal device

Q_b = blood flow to the organ or device

ER = extraction ratio

C_{in} = xenobiotic concentration in fluid (blood or serum) entering the organ or device

C_{out} = xenobiotic concentration in fluid (blood or serum) leaving the organ or device

Clearance can be applied to any elimination process independent of the precise mechanisms (ie, first order, Michaelis-Menten) and represents the sum total of all of the rate constants for xenobiotic elimination. Total body clearance ($Cl_{total\ body}$) is the sum of the clearances of each of the individual eliminating processes, as seen in Equation 9–26:

$$Cl_{total\ body} = Cl_{renal} + Cl_{hepatic} + Cl_{intestinal} + Cl_{chelation} + \dots \quad (\text{Eq. 9-26})$$

For a first-order process (one-compartment model), clearance is given by Equation 9–27:

$$Cl = k_e Vd \quad (\text{Eq. 9-27})$$

Experimentally, the clearance can be derived by examining the IV dose of xenobiotic in relation to the AUC from time zero to time t (Equation 9–28). The AUC is calculated using the trapezoidal rule or through integral calculus (units, eg, {mg \times hour}/mL) (Figs. 9–10 and 9–11).

FIGURE 9–10. The area under the curve (AUC) profile obtained after extravascular administration of a xenobiotic.

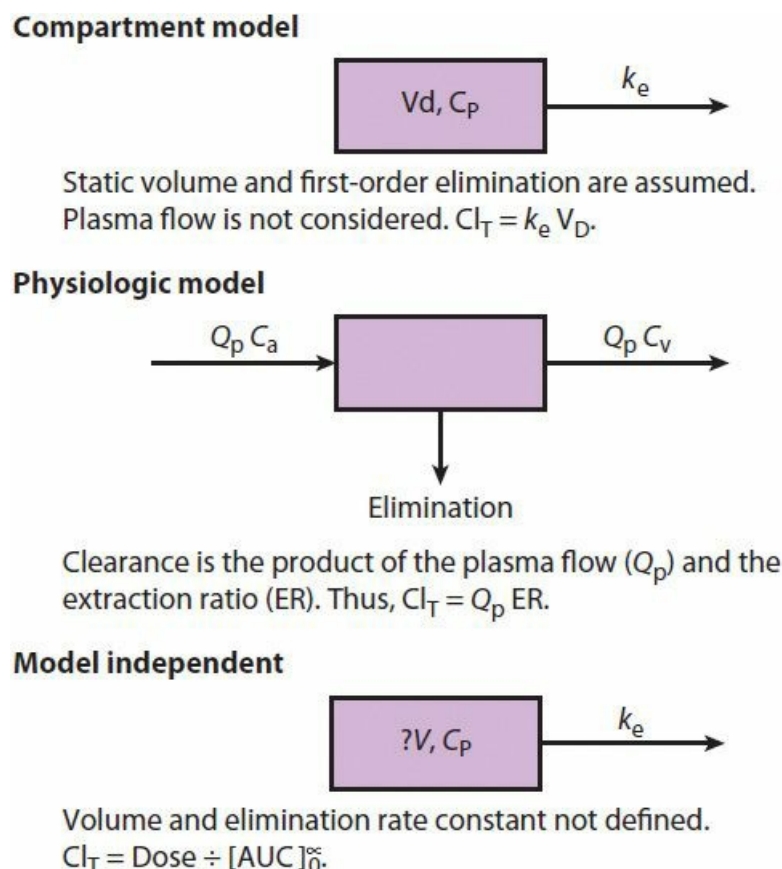

FIGURE 9–11. General approaches to clearance.

$$Cl = \frac{\text{dose}_{IV}}{AUC_{0-t}} \quad (\text{Eq. 9-28})$$

STEADY STATE

When exposure to a xenobiotic occurs at a fixed rate, the plasma concentration of the xenobiotic gradually achieves a plateau concentration at which the rate of absorption equals the rate of elimination and is termed steady state. The time to achieve 95% of steady-state concentration for a first-order process depends on the half-life and usually necessitates 5 half-lives. The concentration achieved at steady state depends on the V_d , the rate of exposure, and the half-life.

Iatrogenic toxicity may occur in the therapeutic setting when dosing decisions are based on serum concentrations determined before achieving a steady state. This adverse event is particularly common when using xenobiotics with long half-lives such as digoxin⁷⁸ and phenytoin.

PEAK PLASMA CONCENTRATIONS

Peak plasma concentrations (C_{\max}) of a xenobiotic occur at the time of peak absorption. At this point in time, the absorption rate is at least equal to the elimination rate. Thereafter, the elimination rate predominates, and plasma concentrations begin to decline. Whereas the C_{\max} depends on the dose, the rate of absorption (k_a), the rate of elimination (k_e), and the time to peak (t_{\max}) are independent of dose and only depend on the k_a and k_e . For the same dose of xenobiotic, if the k_e remains constant and the rate of absorption decreases, then the t_{\max} will occur later, and the C_{\max} will be slightly lower (Table 9–7). Controlled-release dosage forms and xenobiotics that form concretions and have a decreased rate of absorption may not achieve peak concentrations until many hours after an immediate-release preparation with rapid absorption. The AUC will remain the same. However, if the k_a remains constant and the k_e is increased, then the t_{\max} occurs sooner, the C_{\max} decreases, and the AUC decreases (Table 9–7).⁵² Values are based on a single oral dose (100 mg) that is 100% bioavailable ($F = 1$) and has an apparent V_d of 10 L. The drug follows a one-compartment open model. The AUC is calculated by the trapezoidal rule from 0 to 24 hours.

TABLE 9–7. Pharmacokinetic Effects of the Absorption Rate Constant and Elimination Rate Constant

Absorption Rate Constant k_a (h^{-1})	Elimination Rate Constant k_e (h^{-1})	t_{max} (h)	C_{max} ($\mu g/mL$)	AUC ($\mu g \cdot hr/mL$)
0.1	0.2	6.93	2.50	50
0.2	0.1	6.93	5.00	100
0.3	0.1	5.49	5.77	100
0.4	0.1	4.62	6.26	100
0.5	0.1	4.02	6.69	100
0.6	0.1	3.58	6.69	100
0.3	0.1	5.49	5.77	100
0.3	0.2	4.05	4.44	50
0.3	0.3	3.33	3.68	33.3
0.3	0.4	2.88	3.16	25
0.3	0.5	2.55	2.79	20

AUC = area under the (plasma drug concentration versus time) curve; C_{max} = peak xenobiotic concentration; t_{max} = time to peak plasma concentration.

Reproduced with permission from Shargel L, Yu A: Pharmacokinetics of drug absorption. In: *Applied Biopharmaceutics and Pharmacokinetics*. 3rd ed. Norwalk, CT: Appleton & Lange; 1993:183.

In the overdose setting, gastric emptying, single-dose activated charcoal, and WBI decrease k_a . Multiple-dose activated charcoal, manipulation of pH to promote ion trapping to facilitate elimination, and certain chelators (ie, succimer, deferoxamine) increase k_e and are likely to decrease C_{max} , t_{max} , and AUC.

INTERPRETATION OF SERUM CONCENTRATIONS

For serum concentrations to have significance, there must be an established relationship between effect and serum concentration. Many medications, such as valproic acid, digoxin, carbamazepine, lithium, and cyclosporine, have established therapeutic ranges. However, there are also many drugs (eg, diazepam, propranolol, verapamil) for which there is no established therapeutic range. Some xenobiotics (eg, physostigmine) exhibit hysteresis in which the effect increases as the serum concentration decreases. For many xenobiotics, very little information on toxicodynamics is available. Sequential serum concentrations often are collected for retrospective analysis in an attempt to correlate serum concentrations and toxicity. Tolerance to drugs, such as ethanol, also influences the interpretation of serum concentrations. Tolerance is an example of a pharmacodynamic or toxicodynamic effect as a result of cellular adaptation, and it occurs when larger doses of a xenobiotic are necessary to achieve the same clinical or pharmacologic result.

Other factors that influence the interpretation of serum concentrations include chronicity of dosing (a single dose vs. multiple doses); whether absorption is still ongoing and therefore concentrations are still increasing; whether distribution is still ongoing and therefore concentrations are uninterpretable (Fig. 9–12); or whether the value is a peak, trough, or steady-state concentration. Collection of accurate data for analysis requires at least 4 data points during at least 1 elimination half-life. Clinical examples in which interpretation is dependent on the dosing pattern of a single dose versus multiple doses include digoxin, lithium, vancomycin, and APAP. Controlled-release preparations and xenobiotics that delay gastric emptying or form concretions are expected to have prolonged absorptive phases and require serial serum concentrations to obtain a meaningful analysis of serum concentrations (Chap. 6). A combination of trough, peak, and minimum inhibitory concentrations is often consequential for monitoring antibiotics such as gentamicin.^{8,43}

FIGURE 9-12. A theoretical two-compartment model for digoxin. Assume A to E represent the digoxin serum concentration equilibria at different t (time) intervals between the plasma compartment and the tissue compartment. V_i (initial volume of distribution) is smaller than V_t (tissue volume of distribution). The myocardium sits in V_t . E represents distribution at 5 half-lives and it is assumed that the plasma and tissue compartments are now in equilibrium.⁷⁸ (Reproduced with permission from Winter ME: Basic Clinical Pharmacokinetics, 5th edition. Vancouver, WA: Applied Therapeutics; 2010.)

Pitfalls in interpretation arise when the units for a particular serum concentration are not obtained or are unfamiliar (eg, mmol/L) to the clinician. The type of analysis generally applied clinically may not be appropriate to massive overdoses, and the laboratory may make errors in dilution, or errors can be inherent in the assay (Chap. 6). In these cases, the director of the laboratory should be consulted for advice with regard to the availability of a reference laboratory. The type of collection tube (eg, plasma or serum instead of whole blood for certain metals), the receptacle, or the conditions during delivery of the sample result in inaccurate or inadequate information. When in doubt, the laboratory toxicologist or chemist should be called before sample collection. The laboratory usually measures total xenobiotic (free plus bound), and for xenobiotics that are highly plasma protein bound, reductions in albumin increase free concentrations and alter the interpretation of the reported concentration (Equation 9-7). Active metabolites may contribute to toxicity and may not be measured.³⁷ During extracorporeal methods of elimination, ideal criteria for determining the amount removed require assay of the dialysate or activated charcoal cartridge or multiple simultaneous serum concentrations going into and out of the device rather than random serum concentrations (Chap. 10). Clearance calculations for drugs such as lithium that partition significantly into the red blood cells are more accurate when measurements are taken on whole blood.^{13,20} The patient's weight and height and, when indicated, hemoglobin, creatinine, albumin, and other parameters to assess elimination pathways may be helpful.

SUMMARY

- Pharmacokinetics and toxicokinetics are the study of the absorption, distribution, metabolism, and excretion of drugs in the therapeutic and overdose settings, respectively.
- Pharmacokinetics and toxicokinetics can help predict the onset and duration of toxicity when serum concentrations are related to therapeutic and toxic effects.
- Interpretation of serum concentrations relies on many factors dependent on the drugs (eg, dosage form, single versus multiple doses) and the patient (tolerance, genetic profile).

10 PRINCIPLES AND TECHNIQUES APPLIED TO ENHANCE ELIMINATION

David S. Goldfarb and Marc Ghannoum

Enhancing the elimination of a xenobiotic from a poisoned patient is a logical step after techniques to inhibit absorption such as orogastric lavage, activated charcoal, or whole-bowel irrigation have been considered. [Table 10–1](#) lists methods that might be used to enhance elimination. Some of these techniques are described in more detail in chapters that deal with specific xenobiotics. In this chapter, hemodialysis, hemoperfusion, and hemofiltration are considered extracorporeal treatments because xenobiotic removal occurs in a blood circuit outside the body. Currently, these methods are used infrequently because most poisonings are not amenable to removal by these methods. In addition, because these elimination techniques have associated adverse effects and complications, the risk-benefit analysis suggests a benefit in a relatively small proportion of patients.

TABLE 10–1. Potential Methods of Enhancing Elimination of Xenobiotics

<i>Occurring Inside the Body</i>	<i>Occurring Outside the Body (Extracorporeal)</i>
Cerebrospinal fluid replacement	Hemodialysis
Forced diuresis	Hemoperfusion (charcoal, resin)
Manipulation of urine pH	Hemofiltration/Hemodiafiltration
Metal chelators	Exchange transfusion
Multiple-dose activated charcoal	Plasmapheresis
Peritoneal dialysis	
Resins (Prussian blue, sodium polystyrene sulfonate, cholestyramine, colestipol)	

EPIDEMIOLOGY

Although undoubtedly an underestimate of true use, enhancement of elimination was used relatively infrequently in a cohort of approximately 2.4 million patients reported by the American Association of Poison Control Centers (AAPCC) National Poison Data System (NPDS) in 2011 ([Chap. 136](#)).¹² Alkalinization of the urine was reportedly used 10,843 times, multiple-dose activated charcoal (MDAC) 1904 times, hemodialysis 2323 times, and hemoperfusion 14 times. As in the past, there continue to be many instances of the use of extracorporeal treatments that we consider inappropriate, such as in the treatment of overdoses of cyclic antidepressants (CAs).¹²

Although data reporting remains important in comparing the most recent data with past reports ([Table 10–2](#)), there is a continued increase in the reported use of hemodialysis, paralleling a decline in reports of charcoal hemoperfusion ([Chap. 136](#)). Lithium and ethylene glycol were the most common xenobiotics for which hemodialysis was used between 1985 and 2005. Possible reasons for the decline in use of charcoal and resin hemoperfusion are described in the section Hemoperfusion below. Peritoneal dialysis (PD), a slower modality that should have little or no role in any poisoning, is no longer separately reported ([Chap. 136](#)). “Other extracorporeal procedures” in past AAPCC reports may include continuous modalities (discussed below in the section Continuous Hemofiltration and Hemodiafiltration), plasmapheresis, and PD.

^aData derived from American Association of Poison Control Centers annual reports (Chap. 136).

Very few prospective, randomized, controlled clinical trials have been conducted to determine which groups of patients actually benefit from enhanced elimination of various xenobiotics and which modalities are most efficacious. For most poisonings, it is unlikely that such studies will ever be performed, given the relative scarcity of appropriate cases of sufficient severity and because of the many variables that would hinder controlled comparisons. Thus, limited evidence predominates. We must therefore rely on an understanding of the principles of these methods to identify the individual patients for whom enhanced elimination is indicated. Isolated case reports in which the kinetics are studied before, during, and after enhanced elimination are also very useful in establishing the efficacy of a method. Fortunately, in the absence of robust evidence, consensus-based recommendations have now been published and are being developed to guide clinical decisions. The American Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT) published joint position papers on urine alkalinization and MDAC. The Extracorporeal Treatments in Poisoning (EXTRIP) work group, a collaboration of experts from diverse specialties (clinical toxicology, nephrology, pharmacology, critical care, emergency medicine) and represented by more than 30 international societies, is now reviewing the indications for dialysis and other treatments for overdose. Guidelines for several poisons are expected in 2014. See <http://extrip-workgroup.org>.

GENERAL INDICATIONS FOR ENHANCED ELIMINATION

Enhanced elimination may be indicated for several types of patients:

- Patients who fail to respond adequately to comprehensive supportive care. Such patients may have intractable hypotension, heart failure, seizures, metabolic acidosis, or dysrhythmias. Hemodialysis and hemoperfusion (although infrequently used) are much better tolerated than in the past and may represent potentially life-saving opportunities for patients with life-threatening toxicity caused by theophylline, lithium, salicylates, or toxic alcohols.
- Patients in whom the normal route of elimination of the xenobiotic is impaired. Such patients may have kidney or hepatic dysfunction, either preexisting or caused by the overdose. For example, a patient with chronic kidney disease associated with long-term lithium use is more likely to develop toxicity and require hemodialysis as treatment.
- Patients in whom the amount of xenobiotic absorbed or its high concentration in serum indicates that serious morbidity or mortality is likely. Such patients may not appear acutely ill on initial evaluation. Xenobiotics in this group may include ethylene glycol, lithium, methanol, paraquat, salicylates, and theophylline.
- Patients with concurrent disease or in an age group (very young or old) associated with increased risk of morbidity or mortality from the overdose. Such patients are intolerant of prolonged coma, immobility, and hemodynamic instability. An example is a patient with both severe underlying respiratory disease and chronic salicylate poisoning.
- Patients with concomitant electrolyte disorders that could be corrected with hemodialysis. An example is the metabolic acidosis with elevated lactate associated with metformin toxicity discussed in the Hemodialysis section of this chapter.

Ideally, these techniques will be applied to poisonings for which studies suggest an improvement in outcome in treated patients compared with patients not treated with extracorporeal removal. As previously mentioned, these data are rarely available.^{22,26}

The need for extracorporeal elimination is less clear for patients who are poisoned with xenobiotics that are known to be removed by the various modalities of treatment but that cause limited morbidity if supportive care is provided. Relatively high rates of endogenous clearance would also make extracorporeal elimination redundant. Examples of such xenobiotics include ethanol and some barbiturates. Both are subject to substantial rates of hepatic metabolism, and neither would be expected to lead to significant morbidity after the affected patient has had endotracheal intubation and is mechanically ventilated. There may be instances of severe toxicity from these two xenobiotics for which enhanced elimination will reduce the length of intensive care unit (ICU) stays and the associated nosocomial risks; extracorporeal elimination may then be a reasonable option.^{8,50} Dialysis should be avoided if other more effective modalities are

available. For example, a patient with an acetaminophen (APAP) overdose should be initially treated with N-acetylcysteine instead of hemodialysis.

CHARACTERISTICS OF XENOBIOTICS APPROPRIATE FOR EXTRACORPOREAL THERAPY

The appropriateness of any modality for increasing the elimination of a given xenobiotic depends on various properties of the molecules in question. Effective removal by the extracorporeal procedures and other methods listed in [Table 10–1](#) is limited by a large volume of distribution (Vd). The Vd relates to the concentration of the xenobiotic in the blood or serum to the total body burden. The Vd can be envisioned as the apparent volume in which a known total dose of drug is distributed before metabolism and excretion occur:

$$Vd \text{ (L/kg)} \times \text{patient weight (kg)} = \text{Dose (mg)} / \text{Concentration (mg/L)}$$

The larger the Vd, the less the xenobiotic is available in the blood compartment for elimination. A xenobiotic with a relatively small Vd, considered amenable to extracorporeal elimination, would distribute in an apparent volume not much larger than total body water (TBW). TBW is approximately 60% of total body weight, so a Vd equal to TBW is approximately 0.6 L/kg body weight.

Ethanol is an example of a xenobiotic with a small Vd approximately equal to TBW. A substantial fraction of a dose of ethanol could be removed by hemodialysis. In contrast, an insignificant fraction of digoxin with a large Vd (5–12 L/kg of body weight) would be removed by hemodialysis. Lipid-soluble xenobiotics have large volumes of distribution, which typically exceed TBW or even total body weight. These high apparent volumes of distribution imply that the xenobiotic is not available to extracorporeal removal because only a small portion would be in the blood and therefore the extracorporeal circuit. In addition to the alcohols, other xenobiotics with a relatively low Vd include phenobarbital, lithium, salicylates, valproic acid, bromide and fluoride ions, and theophylline. Conversely, those with a high Vd (≥ 1 L/kg of body weight), which would not be removed substantially by hemodialysis, include many β -adrenergic antagonists (with the possible exception of atenolol⁶⁰), diazepam, organic phosphorus compounds, phenothiazines, quinidine, and the CAs.

Pharmacokinetics also influence the ability to enhance elimination of a xenobiotic. Kinetic parameters after an overdose may differ from those after therapeutic or experimental doses. For instance, carrier- or enzyme-mediated elimination processes may be overwhelmed by higher concentrations of the xenobiotic in question, making extracorporeal removal potentially more useful. Similarly, plasma protein- and tissue-binding sites may all be saturated at higher concentrations, making extracorporeal removal feasible in instances in which it would have no role in less significant overdoses. An example is valproic acid, which may be poorly dialyzed at nontoxic concentrations because of high protein binding. However, at higher concentrations, protein-binding sites become saturated and lead to a higher proportion of the drug free in the serum, amenable to removal by hemodialysis at a clinically relevant rate.³⁴ Estimated endogenous elimination of a xenobiotic should be derived by proper toxicokinetic models and not by pharmacokinetic data after therapeutic doses.

When assessing the efficacy of any technique of enhanced elimination, a generally accepted principle is that the intervention is worthwhile only if a large portion of total body drug burden can be eliminated by extracorporeal removal or if total body clearance of the xenobiotic is increased by a factor of 2.⁴¹ This substantial increase is easier to achieve when the xenobiotic has a low endogenous clearance. Examples of xenobiotics with low endogenous clearances (<4 mL/min/kg) include valproic acid, lithium, paraquat, phenytoin, salicylate, and theophylline. Xenobiotics with high endogenous clearances include many β -adrenergic antagonists, lidocaine, opioids, nicotine, and CAs. Enhancement of elimination is expected to contribute more to overall clearance of the former group than to the latter.

The efficacy of any technique of elimination can be directly assessed by comparing the blood or serum concentrations of the xenobiotic at the beginning and the end of the procedure.⁶⁸ For example, a xenobiotic such as theophylline, with one-compartment kinetics, is essentially limited to the extracellular space. The difference between the theophylline concentration before the procedure, minus the concentration at the end of the procedure, divided by the concentration at the beginning, is the fraction of the body burden of the xenobiotic that is eliminated. However, this calculation would not be appropriate to estimate the effect of treatment on the total body burden of a xenobiotic that distributes in a larger Vd or with multicompartment kinetics because the changes in blood concentration may not reflect the effect of the treatment on the total amount in other compartments.

Certain xenobiotics, such as lithium, distribute in part to the intracellular compartment, and equilibrium is established between the intracellular and extracellular compartments. The latter compartment includes the blood from which xenobiotic elimination occurs and the interstitium. An increase in the elimination rate from the extracellular compartment, such as by hemodialysis, alters this equilibrium. The rate of redistribution of the xenobiotic from the intracellular compartment into the now-dialyzed extracellular compartment may be slower than the rate of clearance across the dialysis membrane. In that case, the serum concentration may become relatively low despite a substantial intracellular burden. This low serum concentration reduces the concentration gradient for diffusion from serum to dialysate so that dialysance (the dialysis

clearance) is reduced. Thus, although serum concentrations may decrease precipitously during the procedure, the total-body burden of the xenobiotic may not be affected significantly if it does not move from cells to the dialyzable extracellular volume. An example is a 60-kg patient who ingests 100 (25-mg) amitriptyline tablets, a CA.²² Assuming that the drug is fully absorbed, the 2500-mg distributes in an apparent volume of 40 L/kg of body weight to achieve a serum concentration of 1000 ng/mL, a potentially toxic concentration. If charcoal hemoperfusion is performed with a blood flow rate of 350 mL/min (plasma flow rate of 200 mL/min, assuming a hematocrit of approximately 43%) and the extraction ratio is 100% (see Charcoal Hemoperfusion later), the clearance of drug is 200 mL/min or 200 μ g/min. In 4 hours (240 minutes) of treatment, only 48 mg (48,000 μ g), or less than 2% of the amount ingested, will be removed. The treatment would not have affected toxicity.

Further evidence that a xenobiotic is in a slowly equilibrating compartment is provided by monitoring the serum concentrations after discontinuation of the procedure and demonstrating rebound. This rebound indicates postdialysis redistribution (Fig. 10–1). The magnitude of the rebound depends on total-body stores of the xenobiotic. A postdialysis increase in blood concentration may also result from ongoing absorption from the gastrointestinal (GI) tract.

FIGURE 10–1. Repeated serum lithium concentrations after an acute ingestion. Arrows indicate beginning (green arrows) and end (red arrows) of hemodialysis. After a 5-hour hemodialysis treatment, a significant rebound in serum concentration occurred. An additional 4-hour hemodialysis treatment was then begun.

When assessing overall efficacy, the evidence of enhanced elimination must be considered in the context of the clinical response. In some instances, observed improvement is not predicted by the kinetics of the parent xenobiotic and may not result from the intervention. For example, in severe cases of CA poisoning, unexpected improvement during hemoperfusion could be fortuitous because the toxicity is manifested early and ameliorates rapidly during the initial distribution phase.

Beginning a procedure during the initial distribution phase may increase the fraction of the drug burden that can be removed. Later, after the xenobiotic has distributed into fat or has been bound by plasma or tissue proteins, administration of extracorporeal treatment may have much lower clearance rates and benefits.

The extent of xenobiotic removal by enhanced elimination is not necessarily correlated to clinical improvement. For example, enhanced elimination of phenobarbital by MDAC did not affect clinical outcomes compared with those of overdosed, untreated control subjects despite a decrease in their serum concentrations.⁵³ In another study, no difference was observed between patients with lithium poisoning for whom hemodialysis was done and those for whom it was recommended by a poison control center but not done.⁹ Unfortunately, the study was underpowered and limited by confounding by indication. Similarly, in APAP toxicity, the efficacy of administration of N-acetylcysteine makes extracorporeal removal usually unnecessary. Furthermore, although paraquat exhibits all the chemical characteristics necessary for high extracorporeal removal, the outcome of patients presenting late after paraquat ingestion remains dismal despite active elimination procedures.

Occasionally, there may be unanticipated evidence of improvement despite removal of marginal amounts of the xenobiotic and active metabolites. Some authors have attributed this surprising finding to removal of a critical amount of xenobiotic from a shallow “toxic effect” compartment. This theory has been advanced to explain the response to hemodialysis of patients overdosed with the antipsychotic chlorprothixene³⁹ or with a combination of diltiazem and metoprolol.³ Such effects may lead to transient improvements that are not sustained as drug redistributes from one pool to another, leading to early benefit but eventual recurrence of symptoms. Much of the relevant literature fails to provide long-

term follow-up to demonstrate prolongation of benefits after extracorporeal therapy is completed and xenobiotics have redistributed.

TECHNIQUES TO ENHANCE REMOVAL OF XENOBIOTICS

Although the efficacy of or need for removal of many xenobiotics remains controversial, consensus regarding the indications for a number of procedures has developed. This consensus has led to consistent application of several techniques of enhanced elimination for some toxic exposures that occur relatively more frequently. The techniques to enhance xenobiotic elimination most commonly applied over the past decade have been alkalization of the urine for salicylates and hemodialysis for methanol, ethylene glycol, lithium, and salicylates.

Multiple-Dose Activated Charcoal: “Gastrointestinal Dialysis”

Oral administration of multiple doses of activated charcoal increases elimination of some xenobiotics present in the blood. This modality is discussed in more detail in Antidotes in Depth: A1 and will not be discussed here.

Resins

Resins are sometimes used in poisoning management. They can reduce bioavailability of ingested drugs and act as decontaminants, similarly to activated charcoal. In addition, however, they can enhance elimination of certain xenobiotics by enhancing their back-diffusion from plasma to gut (GI dialysis) and interrupt enterohepatic recirculation.

The most commonly used resins are sodium polystyrene sulfonate (Kayexalate), cholestyramine, and Prussian blue. Sodium polystyrene sulfonate is an ion exchanger that is used regularly for hyperkalemia in patients with chronic kidney disease. Data now exist on its potential use in lithium poisoning, although treatment is limited by hypokalemia.^{25,43} Prussian blue is also an ion exchanger used for treatment of thallium poisoning (Antidotes in Depth: A28). Cholestyramine, a bile acid sequestrant, may bind several xenobiotics, including digoxin, ibuprofen, and mycophenolate mofetil, although its application in poisoning is doubtful (Chap. 65).

Forced Diuresis and Manipulation of Urinary pH

Forced diuresis by volume expansion with isotonic sodium-containing solutions, such as 0.9% sodium chloride and lactated Ringer (LR) solution with or without the addition of a diuretic, may increase renal clearance of some molecules. This therapy would theoretically be most useful for xenobiotics such as lithium for which the glomerular filtration rate (GFR), which is the volume of plasma filtered across the glomerular basement membrane per minute, is an important determinant of excretion. In people with normal extracellular fluid (ECF) volume who have not had loss of sodium via renal, GI, or other routes of excretion, the increase in GFR expected with plasma volume expansion is variable and unpredictable and may not lead to significant increases in xenobiotic elimination. The effect is potentially more important in patients who have had contraction of the ECF volume because of sodium loss. Loss of extracellular volume leads to a reduction of GFR partly as a result of decreased cardiac preload and cardiac output, which, in turn, reduces renal plasma flow. This circumstance is also accompanied by activation of angiotensin II, a small peptide that acts as a pressor and stimulates sodium reabsorption in the proximal tubule. Because small molecules such as lithium are both filtered at the glomerulus and reabsorbed by the proximal tubule, especially when sodium depletion has occurred and angiotensin II has been activated, repletion of ECF volume with 0.9% sodium chloride will increase GFR and suppress sodium reabsorption. The result is an increase in excretion of low-molecular-weight xenobiotics such as lithium. After the ECF volume is restored, the continued infusion of 0.9% sodium chloride or LR increases urine volume proportionally more than GFR, which may increase excretion of some small molecules such as urea, but which has little efficacy in the case of most poisonings.

The significant risk of excessive volume repletion is ECF volume overload, manifested by pulmonary and cerebral edema. This complication may be particularly likely in patients with long-standing lithium use in whom chronic tubulointerstitial disease may lead to chronic kidney disease that does not improve with fluid therapy. Other patients with acute kidney injury not mediated by ECF volume depletion are also at risk. Knowing the result of past serum creatinine concentrations may help distinguish acute from chronic kidney disease in such cases. Administration of diuretics such as furosemide along with saline may diminish the risk of ECF volume overload but may complicate the therapy, confuse the assessment of ECF volume, and increase the risk of metabolic alkalosis and hypokalemia. The unproven efficacy of forced diuresis in the management of any overdose has led most experts to abandon its use. On the other hand, the repletion of ECF volume when volume contraction is present, as determined by the history and physical examination, is, of course, appropriate.

Many xenobiotics are weak acids or bases that are ionized in aqueous solution to an extent that depends on the pK_a of the xenobiotic and the pH of the solution. Knowing these variables, the Henderson-Hasselbalch equation (Chap. 9) may be used to determine the relative proportions of the acids, bases, and buffer pairs. Whereas cell membranes are relatively

impermeable to ionized, or polar molecules (eg, an unprotonated salicylate anion), nonionized, nonpolar forms (eg, the protonated, noncharged salicylic acid) may cross more easily. As xenobiotics pass through the kidney, they may be filtered, secreted, and reabsorbed. If the urinary pH is manipulated to favor the formation of the ionized form in the tubular lumen, the xenobiotic is trapped in the tubular fluid and is not passively reabsorbed into the bloodstream. This is referred to as ion trapping. Hence, the rate and extent of its elimination can be increased. To make manipulation of urinary pH worthwhile, the renal excretion of the xenobiotic must be a major route of elimination. The 2004 position paper of the AACT and EAPCCT emphasizes that, as discussed above for extracorporeal therapies, enhanced removal does not necessarily translate into a clinical benefit with improved outcomes.⁵⁶

Alkalinization of the urine to enhance elimination of weak acids has a limited role for xenobiotics such as salicylates,⁴⁸ phenobarbital, chlorpropamide, formate, diflunisal, fluoride, methotrexate, and the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D). These weak acids are ionized at alkaline urine pH, and tubular reabsorption is thereby greatly reduced. Alkalinization is achieved by the intravenous administration of sodium bicarbonate (1 to 2 mEq/kg rapid initial infusion with additional dosing) to increase urinary pH to 7 to 8.

This degree of alkalinization may be difficult, if not impossible, if metabolic acidosis and acidemia are present, as often is the case in patients with salicylate poisoning. In this situation, bicarbonate (administered as the sodium salt, sodium bicarbonate) is consumed by titration of plasma protons before it can appear in the urine. On the other hand, salicylate poisoning often causes respiratory alkalosis as well. In that case, when the PCO₂ is low, raising serum bicarbonate, equivalent to the induction of metabolic alkalosis, may lead to profound, life-threatening alkalemia. Finally, the risk of ECF volume overload with sodium bicarbonate administration is the same as with the administration of 0.9% sodium chloride or LR. Hypernatremia may also occur after administration of hypertonic sodium bicarbonate. Bicarbonaturia is also associated with urinary potassium losses, so the patient's serum potassium concentration should be monitored frequently and KCl given liberally as long as GFR is not impaired. A further complication of alkalemia is a decrease of ionized calcium, which becomes bound by albumin as protons are titrated off serum proteins; in this event, tetany may occur.²¹ If these complications can be identified and dealt with judiciously and safely, the renal clearance of salicylate may increase fourfold as urine pH increases from 6.5 to 7.5 with alkalinization. Increasing urine pH by decreasing proximal tubular bicarbonate reabsorption via administration of carbonic anhydrase inhibitors such as acetazolamide is not recommended. Although elimination of a xenobiotic may be increased, metabolic acidosis will ensue unless ample sodium bicarbonate is also administered. In the case of salicylates, metabolic acidosis with acidemia increase distribution into the central nervous system. As with sodium bicarbonate administration, bicarbonaturia is accompanied by urinary potassium losses; hypokalemia may be profound. The role of urinary alkalinization in the management of patients with salicylate poisoning is discussed further in [Chap. 39](#).

Alkalinization is also used to increase the solubility of methotrexate and thereby prevents its precipitation in tubules when patients are given high-dose methotrexate.¹³ Precipitation of sulfonamide antibiotics with kidney stones or kidney failure may also be prevented by alkalinization. Administration of sodium bicarbonate, sodium chloride, or LR also protects the kidneys from the toxic effects of myoglobinuria in patients with extensive rhabdomyolysis. However, because patients with rhabdomyolysis may have acute kidney injury, sodium bicarbonate administration must be used before kidney injury occurs and may lead to ECF volume overload if its administration continues after kidney failure has developed.

Acidification of the urine by systemic administration of HCl or NH₄Cl to enhance elimination of weak bases, such as phencyclidine or the amphetamines, is not useful and is potentially dangerous. The technique has been abandoned because it does not significantly enhance removal of xenobiotics and is complicated by acidemia.

Peritoneal Dialysis

Theoretically, PD enhances the elimination of water-soluble, low-molecular-weight, non-protein-bound xenobiotics with a low V_d. Clearance of xenobiotics by PD is related to the number of exchanges, dwell time of dialysate, the surface area of the peritoneum, and the molecular weight of the compound. The highest clearances are achieved for xenobiotics with molecular weights below 500 Da. The efficacy of PD is markedly decreased when the patient is hypotensive.

Although PD is a relatively simple method to enhance xenobiotic elimination, it is too slow to be clinically useful. Consequently, PD is never the method of choice unless hemodialysis and hemoperfusion are unavailable and transfer to a center that can offer these techniques is not feasible. Besides exchange transfusion, it may be the only practical option in small children when experience with extracorporeal techniques in younger age groups is lacking or until a child can be transported to an appropriate center.

Hemodialysis

Hemodialysis has been employed for 100 years, ever since the discovery by John J. Abel and coworkers that dialysis could remove substantial amounts of salicylates from animals.¹ During conventional hemodialysis, blood and countercurrent dialysate are separated by a semipermeable membrane (dialyzer). Xenobiotics then diffuse across the membrane from blood into the dialysate down the concentration gradients ([Fig. 10–2](#)). Blood is pumped through one lumen of a temporary

dialysis catheter, passed through the machine, and returned to the venous circulation through the second lumen.

FIGURE 10–2. The comparative schematic layouts of hemodialysis (HD), continuous venovenous hemofiltration (CVVH), continuous venovenous hemofiltration with dialysis (CVVHD), and hemoperfusion (HP). Red circles ● are high molecular-weight (MW) xenobiotics, such as methotrexate, whose high MW makes them too large to be removed by HD; Yellow circles ● are low MW diffusible solutes such as urea or methanol. In dialysis, solute moves across a semipermeable membrane (dashed lines) from a solution in which it is present in a high concentration (blood) to one in which it is at a low concentration (dialysate). In CVVH and CVVHD, plasma moves across a similar membrane in response to hydrostatic pressures; replacement fluid must be provided. The latter also utilizes a dialysate to augment clearance. The availability of blood pumps has made arteriovenous modalities nearly obsolete. Charcoal hemoperfusion (CH) requires movement of blood through a sorbent-containing cartridge and does not include dialysis or hemofiltration.

The utility of hemodialysis for the treatment of patients with toxicity caused by lithium, toxic alcohols, salicylates, or theophylline is unquestionable and is not dealt with here; each of these xenobiotics is described in detail in separate chapters that also review their toxicity and indications for extracorporeal therapies. This section describes the hemodialysis procedure in general and its application to some newer situations.

Prompt consultation with a nephrologist is always indicated in the case of poisoning with a xenobiotic that might benefit from extracorporeal removal. Annual AAPCC data consistently suggest that some salicylate-related deaths, for example, could have been prevented if hemodialysis had been instituted earlier ([Chap. 136](#)).¹⁹ To perform hemodialysis, a nephrologist must be available along with a nurse or technician. The dialysis machine requires preparation, and a vascular access catheter must be inserted. A delay, ranging from one to several hours before hemodialysis can be instituted should be anticipated, particularly during hours when the hospital's dialysis unit, if there is one, is closed. If indicated, modalities of treatment such as fomepizole or ethanol for poisoning with toxic alcohols should be administered and other modalities to enhance elimination, such as urinary alkalization or oral MDAC, should be used when appropriate.

The technical details of performing hemodialysis for treatment of patients with poisonings do not differ markedly from those used in the treatment of patients with acute kidney failure. Several technologic advances have enabled improved xenobiotic clearance while limiting side effects and enabling better tolerance of dialysis.

Vascular access is obtained via a double-lumen catheter that is made of silicon, polyethylene, polyurethane, or Teflon. The catheter is usually inserted either via the femoral, the subclavian, or the jugular vein. The subclavian and internal jugular veins have the added risk of pneumothorax and necessitate radiographic confirmation of catheter position, whereas femoral catheters have increased blood recirculation (ie, lower efficacy of approximately 10% to 15%).⁴² Hemostasis after catheter removal is also more easily achieved at the femoral site. Bleeding or thrombosis at the site used for vascular access occur in approximately 5% of cases but can usually be addressed by adequate post-procedure tamponade of the catheter site. Ultrasonographic placement reduces the risk of complication for all sites and is now recommended in the United States. Larger catheters now permit blood flow rates that can be as high as 450 to 500 mL/min, although 350 mL/min may sometimes be the maximum rate achievable. Nosocomial bacteremia may occur when central catheters are indwelling but are exceedingly rare if they are in place for less than 3 days. This complication is therefore unusual in poisoning where extracorporeal treatment is necessary for a relatively short period of time. Femoral venous lines should always be removed in patients who are mobile and out of bed.

Because new dialysis membranes also have higher water permeability, computerized ultrafiltration control is necessary. These membranes, composed of polysulfone, polyamide, polyacrylonitrile, and other synthetic polymers, have better biocompatibility than older, cellulose-derived membranes. Biocompatibility is measured by the rate of activation or release, after exposure to the membrane, of inflammatory mediators that include white blood cells, platelets, complement, and cytokines. Better biocompatibility means less activation of these potentially damaging mechanisms compared with more bioincompatible membranes. The influence of biocompatibility on the outcomes of patients receiving long-term hemodialysis for chronic kidney failure is still being assessed. Patients with end-stage kidney failure are exposed to these membrane materials during at least three treatments a week for many years. It is unlikely that better biocompatibility will affect outcomes for dialysis of poisoned patients who require only one or two treatments.

Dialysis membrane composition has also continually evolved. The hollow-fiber dialyzer, almost universally used today, is composed of thousands of blood-filled capillary tubes held together in a bundle and bathed in the machine-generated dialysate. Older "conventional" dialyzers, much less frequently encountered today, are made of cellulose-derived polymers, most commonly called cuprophane. Hemodialysis efficacy for poisonings with low-molecular-weight xenobiotics should improve with the use of larger membranes with larger clearances. "High-flux," synthetic dialyzers have larger pores and increased surface area that allow greater clearance of larger molecules. With the use of high-flux and high-efficiency dialyzers, small molecule clearance has more than doubled, whereas clearance of larger molecules, such as β_2 -microglobulin (molecular weight, 11,800 Da) have increased by a factor of five. There are some instances in which high-flux dialyzers might be important in promoting clearance of larger molecules, such as vancomycin (molecular weight, 1449 Da), which are not readily removed by conventional low-flux membranes.²⁴ However, the indications for performing hemodialysis to enhance removal of vancomycin and other xenobiotics with higher molecular weights have not been delineated. Nonetheless, a sound pharmacologic basis for the efficacy of dialysis must still be present; no amount of increased clearance will eliminate a xenobiotic with a large V_d or significant protein or tissue binding. Although clearance rates reported in the literature of the 1970s and 1980s may significantly underestimate currently achievable clearance rates,⁵⁰ these data are still of interest given the relative paucity of more recent reports.

Patients undergoing hemodialysis experience much less hemodynamic instability than in the past; the blood lines and artificial kidney (the dialysis membrane) should be primed with an appropriate volume of fluid to reduce or avoid hypotension when the procedure is started. Furthermore, the source of base in dialysate is now routinely sodium bicarbonate rather than sodium acetate; the latter caused hypotension and decreased cardiac output. Computerized machines allow fine control of ultrafiltration rates to limit volume losses; in the past, imprecise calculations and manipulations led to frequent episodes of hypotension. As a result of such innovations, treatment can be delivered in more instances than was previously possible. Hypotension may still occur in critically ill patients but can often be corrected with 0.9% sodium

chloride, colloid, vasopressors, or inotropes.

Full anticoagulation with heparin is usually required to avoid clotting of the circuit. A typical adult heparin dose is 1000 to 5000 units as a bolus followed by 500 to 1000 units hourly, but lower doses can also be given. Alternatively, in patients at high risk of bleeding, periodic 0.9% sodium chloride flushes of the dialysis membrane may suffice. Use of a dialysate that contains citrate may be adequate for anticoagulation and may allow heparin to be avoided. These choices are particularly important when dialyzing patients for toxic alcohol and salicylate exposures who are at risk for increased intracerebral bleeding.

In poisoned patients, hemodialysis is usually performed for 4 to 8 hours. Some precautions are needed for the prescription of the dialysis parameters because poisoned patients have different characteristics than chronic kidney disease patients. In particular, serum potassium, phosphorus, and pH can be markedly different. Assuming that the patient's serum potassium concentration is normal, a standard bicarbonate-based dialysate with a potassium concentration of 3 or 4 mEq/L and a calcium concentration of 3 mEq/L, flowing at 600 to 800 mL/min, is sufficient. If dialysis is performed in a dialysis unit, the dialysate is a mix of a concentrate with sodium bicarbonate and highly purified water, usually derived by reverse osmosis or deionization. Phosphate can be added to the dialysate bath if needed. Ultrafiltration is rarely required unless oliguric acute kidney injury is present. Dialysis procedures done in ICUs should use portable reverse osmosis machines to generate the water for mixing. Although undesirable, tap water can be used if its chlorine content is less than 0.1 ppm.⁷

Complications specifically related to the dialysis procedure are rare. Furthermore, centers administering dialysis treatments are increasingly common today, and costs of the procedure are on the decline. For these reasons, if dialysis appears required for survival of a poisoned patient, it should usually be attempted.

Table 10–3 lists the characteristics of xenobiotics that make them amenable to hemodialysis. These requirements greatly reduce the number of xenobiotics that can be expected to be cleared by dialysis. During hemodialysis, clearance of a xenobiotic (Cl_x) can be calculated by:

TABLE 10–3. Characteristics of Xenobiotics That Allow Clearance by Hemodialysis, Hemoperfusion, and Hemofiltration

<i>For All Three Techniques</i>	<i>For Hemodialysis</i>	<i>For Hemoperfusion</i>	<i>For Hemofiltration</i>
Low Vd (<1 L/kg)	MW <5000 Da	Adsorption by activated charcoal	MW <40,000 Da
Single-compartment first order kinetics	Water soluble	Binding by plasma proteins does not preclude	
Low endogenous clearance (<4 mL/min/kg)	Not bound to plasma proteins		

MW = molecular weight; Vd = volume of distribution.

$$Cl_x = Q_p \times ER$$

where Q_p is the plasma flow rate and ER is the extraction ratio.

$$Q_p = Q_b \times (1 - Hct)$$

where Q_b is blood flow rate and Hct is hematocrit. The ER is a measure of the percentage of xenobiotic passing through the artificial kidney or charcoal hemoperfusion cartridge. This can be calculated as:

$$ER = \frac{C_{in} - C_{out}}{C_{in}} \times 100$$

where C_{in} is the concentration of the xenobiotic in blood entering the system and C_{out} is the concentration in blood leaving the system.

Thus:

$$Cl_x = [Q_p (C_{in} - C_{out})] / C_{in}$$

With the recent advances in dialysis therapy, there appears to be a role for high-flux hemodialysis in the clearance of certain xenobiotics that were previously thought to be effectively removed only by charcoal hemoperfusion.²³ The

situations in which these modalities are appropriate for these xenobiotics remain exceedingly rare. Because valproic acid is increasingly prescribed for neurologic and psychiatric disorders, the incidence of both intentional and unintentional overdoses of this drug will also increase.⁶⁷ As discussed previously, valproic acid is largely protein bound at therapeutic serum concentrations. Toxic concentrations saturate protein-binding sites, leading to a higher proportion of unbound drug in the serum and a lower apparent Vd, thereby making the drug more dialyzable. Indeed, several case reports have demonstrated that the clearance of valproic acid with high-flux hemodialysis is at least equivalent to, if not greater than, that of charcoal hemoperfusion.^{29,38} Although carbamazepine has a low molecular weight and a Vd that would allow for clearance by hemodialysis, its high protein binding and lack of water solubility are expected to impede the efficacy of hemodialysis. Nonetheless, carbamazepine is also effectively cleared by high-flux hemodialysis.⁶¹ In a patient who underwent high-flux hemodialysis followed by charcoal hemoperfusion for carbamazepine toxicity, removal rates were similar for the two modalities.⁶⁹ Unlike the case of valproic acid, the rationale for these anecdotal reports for enhanced carbamazepine elimination is unclear. Whether the pharmacokinetics of the drug are altered at toxic serum concentrations, as are those of valproic acid, is not known. Because of its potential efficacy and availability and its insignificant effect on cost and adverse events, high-flux hemodialysis should probably replace charcoal hemoperfusion as the treatment modality of choice when extracorporeal elimination is to be performed. As stated above, however, effective clearance is not necessarily a surrogate for improved outcomes.

In addition to removing xenobiotics, hemodialysis can correct acid–base and electrolyte abnormalities such as metabolic acidosis or alkalosis, hyperkalemia, and ECF volume overload. Consequently, hemodialysis is preferred, if not essential, for poisonings characterized by these disorders, especially when clearance rates resulting from hemoperfusion and hemodialysis are relatively similar. Examples include salicylate poisoning, which is often associated with metabolic acidosis,³² and propylene glycol toxicity, which is often associated with lactic acidosis, especially in the presence of renal or hepatic impairment.⁵² Valproic acid toxicity causes hyperammonemia, which is reduced by hemodialysis, possibly contributing to the benefit of the procedure.⁷⁰

A more controversial question is the role of dialysis in the treatment of metformin-associated lactic acidosis. Although debated, present evidence now suggests that metformin intoxication itself may induce metabolic acidosis with elevated lactate concentration without predisposing factors.^{2,55} Here, the small molecular weight and negligible plasma protein binding of metformin may allow for adequate drug removal despite a relatively large Vd. Endogenous clearance of metformin is quite high and dialysis has therefore less appeal in patients with intact kidney function. In addition, hemodialysis would rapidly correct acidosis via administration of sodium bicarbonate without the complication of volume overload. Clinical improvement with hemodialysis may result as much or more from rapid correction of the acidosis as from removal of the drug.

In addition, hemodialysis increases the elimination of some drugs administered therapeutically, such as folic acid and other water-soluble vitamins and xenobiotics. Doses of these drugs should be increased during dialysis or administered immediately afterward. Similarly, the rate of ethanol infusions used in the treatment of patients with toxic alcohol ingestions must be increased. Fomepizole also has a low molecular weight (molecular weight, 82.1 Da) and a low Vd (0.6–1.0 L/kg), so it can also be dialyzed. If necessary, it should be redosed after dialysis (Antidotes in Depth: A30). When fomepizole is not available, ethanol removal can be limited in such cases by enriching the dialysate with ethanol to a concentration of 100 mg/dL.¹⁴ Similarly, hypophosphatemia after more prolonged high-flux hemodialysis can be avoided by adding sodium phosphate salts (eg, Fleet Phospho-Soda) to the dialysate or by administering phosphate intravenously.

Hemoperfusion

During hemoperfusion, blood is pumped via a catheter through a cartridge containing a very large surface area of sorbent, either activated charcoal or a resin, on to which the xenobiotic can be directly adsorbed (Fig. 10–2). The activated charcoal sorbent is coated with a very thin layer of polymer membrane such as cellulose acetate (Adsorba: Gambro, Lakewood, CO), heparin-hydrogel (Biocompatible Hemoperfusion Systems: Clark, New Orleans, LA) or polyHEMA (2-hydroxyl methacrylate or Hemosorba: Asahi, Tokyo, Japan). The membrane prevents direct contact between blood and sorbent, improves biocompatibility, and helps prevent activated charcoal embolization. There may be a further theoretical advantage to the heparin–hydrogel coating to diminish platelet aggregation.

Other adsorptive resins were used for hemoperfusion in the past, such as the synthetic Amberlite XAD-2 and XAD-4 and anion exchange resins such as Dow 1X-2. None of these columns is currently approved or available for use in the United States, but remain available in other countries. The literature regarding their efficacy is scant and relatively anecdotal. Although in vitro evidence suggests that these resins may have greater adsorptive capacities than activated charcoal, there are few, if any, meaningful comparisons in a clinical setting.

The adsorptive capacity of the cartridge is reduced with use because of deposition of cellular debris and blood proteins and saturation of active sites by the xenobiotic in question. Hemoperfusion is usually performed for 4 to 6 hours at flow rates that can usually not exceed 350 mL/min because of the risk of hemolysis.⁵⁸ The technique can be used in adults¹⁵ or children.⁵¹

The characteristics of xenobiotics that make them amenable to hemoperfusion (Table 10–3) differ slightly from those for hemodialysis in that hemoperfusion is not as limited by plasma protein binding, although this is less true with the advent of new dialysis membranes which now permit removal of significant amounts of highly bound xenobiotics.²⁷ Some xenobiotics are poorly adsorbed by activated charcoal, including the alcohols, lithium, and many metals (Antidotes in Depth: A1), making hemoperfusion inappropriate in their management. Hemodialysis and hemoperfusion have been performed in series for procainamide, thallium, theophylline, and carbamazepine overdoses, with greater apparent clinical efficacy than with either procedure alone.^{10,17,37} In this technique, blood circulates first through the hemodialysis membrane and then through the activated charcoal cartridge. If blood traverses the dialysis membrane first, some of the xenobiotic is dialyzed, and the activated charcoal cartridge has less drug to adsorb.³¹

Added to the questionable benefits of hemoperfusion, multiple limitations make their use less attractive when compared to hemodialysis. A practical problem limiting the use of charcoal hemoperfusion is the availability of the cartridges. Many dialysis units do not currently stock these cartridges.⁶⁴ Activated charcoal cartridges were more available in hemodialysis units when they were more frequently needed for the treatment of patients with chronic aluminum toxicity. Saturation of the cartridge is apparent within 1 hour of use and markedly decreases absorptive capacity at 2 hours, whereas no such decreased performance is apparent with hemodialyzers. Compared with hemodialysis, patients must be anticoagulated with greater amounts of heparin. The cartridges are expensive (\$350–\$425 compared with the maximal cost for a high-flux dialysis membrane at about \$40–\$50), especially considering cartridges usually need to be replaced every 2 hours. Some have expiration dates, limiting their shelf life. Others, such as the Clark system, have an indefinite shelf life but must be autoclaved before use, which may affect their availability in an emergency. Complications of hemoperfusion are more common than with hemodialysis: thrombocytopenia, leukopenia, and hypocalcemia.⁶⁵ Finally, hemoperfusion cannot correct acid–base or electrolyte abnormalities and cannot provide ultrafiltration if volume overload occurs.

Although hemoperfusion has historically been considered the preferred method to enhance the elimination of carbamazepine, phenobarbital, phenytoin, and theophylline (Table 10–4), recent improvements in hemodialysis technology may make older comparisons of hemodialysis and hemoperfusion clearance rates obsolete. The most frequent indication for charcoal hemoperfusion in the past was theophylline toxicity, and theophylline is rarely used today in the treatment of obstructive lung disease and asthma and is consequently less often implicated in acute and chronic poisoning. Along with the rarity of aluminum toxicity in chronic hemodialysis patients, the infrequency of theophylline prescription accounts for the diminished availability of activated charcoal cartridges and the relative infrequency with which the procedure is performed. In a survey of New York City hospital dialysis units taking 911 calls, only 10 of 34 units had cartridges.⁶⁴ In a review of the AAPCC annual data, theophylline was the most common xenobiotic removed by hemoperfusion from 1985 to 2000, but carbamazepine became the most frequent xenobiotic removed by hemoperfusion during 2001 to 2005.³⁰ As in the case of hemodialysis, doses of drugs used therapeutically may need to be increased if they are removed by hemoperfusion.

TABLE 10–4. Properties of Xenobiotics Grouped by Benefit of Extracorporeal Techniques for Elimination

Xenobiotic	MW (Da)	Water Soluble	Vd (L/kg)	Protein Binding (%)	Endogenous Clearance (mL/min/kg)	Comments
Clinically Beneficial						
Bromide	35	Yes	0.7	0	0.1	Falsely elevated chloride measurement
Caffeine	194	Yes	0.6	36	1.3	
Ethylene glycol	62	Yes	0.6	0	2.0	May have osmolar, kidney failure
Diethylene glycol	106	Yes	0.5	0	NA	Renal failure
Isopropanol	60	Yes	0.6	0	1.2	No anion gap acidosis
Lithium	7	Yes	0.8	0	0.4	Cl ↓ in kidney failure
Methanol	32	Yes	0.6	0	0.7	Risk of CNS hemorrhage
Propylene glycol	76	Yes	0.6	0	1.7	Lactic acidosis, possible acute kidney injury
Salicylate	138	Yes	0.2	50	0.9	Cl and protein binding ↓, with ↑ dose; HD also corrects electrolytes, acid-base disturbance
Theophylline	180	Yes	0.5	56	0.7	HF and HD can also be combined
Valproic acid	144	Yes	0.2	90	0.1	↑ Concentrations associated with ↓ % protein binding
Possibly Clinically Beneficial						
Amatoxin	373–990	Yes	0.3	0	2.7–6.2	Possibly effective if performed within the first 24 hours of exposure
Aminoglycosides	>500	Yes	0.3	1.5	<10	Cl ↓ with kidney failure
Atenolol	255	Yes	1.0	2.5	<5	Useful if Cl ↓ caused by kidney failure
Carbamazepine	236	No	1.4	74	1.3	Cl ↑ in patients on long-term therapy
Disopyramide	340	No	0.6	1.2	90	Protein binding ↓ as concentration ↑
Fluoride	19	Yes	0.3	50	2.5	Hypocalcemia may be improved by HD; may add little if endogenous renal clearance is preserved
Methotrexate	454	Yes	0.6	50	1.5	Urine alkalinization is indicated
Paraquat	186	Yes	1.0	6	24.0	Tight tissue binding precludes efficacy unless initiated early
Phenobarbital	232	No	0.5	24	0.1	Only for prolonged coma
Phenytoin	252	No	0.6	90	0.3	Cl ↓, as dose ↑

Cl = clearance; HD = hemodialysis; HF = hemofiltration; HP = hemoperfusion; MW = molecular weight; NA = not available; Vd = volume of distribution.

Liver Dialysis

A newer concept for poisonings is that of liver dialysis. These procedures are currently available in the United States, mostly for the treatment of liver failure. Several techniques have been developed; the following three are the most common. (1) Single pass albumin dialysis (SPAD) is similar to hemodialysis but has albumin added to the dialysate in counter-directional flow and then discarded after passing through a filter. (2) The Molecular Adsorbents Recirculation System (MARS) is identical to SPAD, but the albumin-enhanced dialysate (with the adsorbed xenobiotics) is itself recycled after going through another dialysis circuit and through both resin and activated charcoal cartridges. (3) The Prometheus system is a device that combines albumin adsorption with high-flux hemodialysis after selective filtration of the albumin fraction through a polysulfone filter. In all of these techniques, the dialysate bathing the fibers contains human serum albumin that serves as a sorbent to bind the xenobiotic of interest and maintain concentrations of the free xenobiotic at zero. A steep concentration gradient from blood to dialysate is established so that even highly protein-bound xenobiotics can be removed

from the plasma. The membrane is impermeable to albumin, which remains in the dialysate.

These extracorporeal devices are all able to remove protein-bound xenobiotics, but their use in poisoning remains limited to rare case reports. These devices are mostly used in patients with hepatic encephalopathy and liver failure and as a bridge to hepatic transplantation.^{47,66} In toxicology, their use is mostly described in hepatic failure following toxicity of APAP or *Amanita* spp. exposure (Chap. 120). The reasons why the procedure might offer significant benefits are not completely understood, although it does remove both water-soluble and protein-bound compounds. It is not known which protein-bound molecules are removed from the blood, such as bile salts and aromatic amino acids, to account for the therapeutic advantage in hepatic failure. Specific uses for liver dialysis for elimination enhancement has been described in poisoning with phenytoin,⁶³ theophylline,⁴⁰ valproic acid,¹⁸ and *Amanita* mushrooms.³⁶ Whether this relatively expensive (in excess of \$4000 per treatment), complicated, and nonspecific procedure would offer benefit in a handful of instances in which protein-binding limits removal of xenobiotics is not known. The report of the initial use of a sorbent-based hemodiabsorption device in 10 cases of CA overdoses claimed benefit, although the limitations of extracorporeal therapy for this particular class of drugs are discussed above.⁶ Devices using powdered sorbent are not currently available in the United States.

Continuous Hemofiltration and Hemodiafiltration

Hemofiltration is the movement of plasma across a semipermeable membrane in response to hydrostatic pressure (convection). The addition of dialysate on the other side of the membrane further enhances elimination of xenobiotics or endogenous uremic toxins. A review of continuous modalities of dialytic therapy concluded that they are still relatively unproven for the treatment of poisoning.²⁸ These techniques find relatively widespread usage for the treatment of patients with acute kidney injury in the ICU, and in this context, they are referred to collectively as modalities of continuous renal replacement therapy (CRRT). The clearances of either urea or xenobiotics that are achieved with these techniques are significantly lower than those achieved with hemodialysis. But as continuous modalities, what they lack in clearance they can make up for in time.

There are several possible advantages of continuous modalities. One is the capability to continue therapy for 24 hours every day, permitting hemofiltration to be instituted after hemodialysis or hemoperfusion to further remove a xenobiotic after it redistributes from tissue to blood.⁴⁶ This is an attractive modality for slow, continuous removal of drugs, such as lithium, which distribute slowly from tissue-binding sites or from the intracellular compartment (Fig. 10–1). Other xenobiotics with volumes of distribution that are large enough to preclude use of dialysis or hemoperfusion might also be eliminated with longer courses.

Table 10–3 summarizes the properties of xenobiotics that make them amenable to hemofiltration. However, the rate of removal with this form of therapy may be insufficient to benefit critically ill patients. Patients who can tolerate slower clearance rates may not require this enhanced elimination therapy at all. Whether slow treatment to avoid redistribution of intracellularly distributed lithium, for example, is preferable to repeating conventional hemodialysis is unclear.^{45,71} Rebound of serum concentrations indicates that the drug is moving out of the intracellular compartment, where it is toxic, into the extracellular compartment, where it is susceptible to removal by hemodialysis. Therefore, although the continuous modalities are suggested to prevent rebound, the importance of this property, during which poison in the toxic compartment is actually decreasing while plasma concentrations actually increase, remains unproven and may in fact be desirable. Despite many case reports demonstrating significant xenobiotic clearance, no data have demonstrated that these continuous techniques affect prognosis or mortality in treatment of patients with xenobiotic toxicity. In most cases, hemodialysis should be considered the preferred initial mode of therapy.

The continuous modalities may be best suited for patients with hypotension who cannot tolerate conventional hemodialysis, although this situation is infrequent unless oliguric acute kidney injury is present.¹¹ These modalities may also have a role after hemodialysis to avoid the need for a repeat session after equilibration of the xenobiotics into plasma. The continuous modalities may also have a slight advantage over the use of high-flux hemodialysis membranes, in being able to clear larger molecules such as myoglobin (molecular weight, 17,000 Da). Growing evidence suggests that a significant part of the clearance of many molecules occurs because of adsorption of the molecule to synthetic membranes.¹⁶ However, quantification of the contribution of adsorption to total clearance is difficult and is not usually accomplished in published studies. Adsorption of molecules responsible for adverse effects is being studied as a potential benefit in the management of cytokines and liver failure and could be a property useful in the management of poisoning.⁵⁷ At present, this property is difficult to quantify and of uncertain benefit. Another practical advantage of CRRT is that the procedure is usually done now in ICUs by ICU nurses, and when available in such units, might not require dialysis personnel. Familiarity of ICU staff with the procedure is critical to its availability when needed; it is most likely to be used effectively in hospitals with higher incidence rates of acute kidney injury.

In pure hemofiltration, sometimes called slow continuous ultrafiltration (SCUF), there is no dialysate solution on the other side of the dialysis membrane (Fig. 10–2). Molecules are transported across the membrane with plasma water, a mechanism known as convective transport or bulk flow. The ECF volume status of the patient determines whether

replacement of all or some of the filtered plasma with physiologic electrolyte solution (LR or other commercially available preparations) is indicated. Although this technique can be done intermittently using a hemodialysis machine, it has been adapted for use in ICUs as a continuous form of treatment, particularly when removal of ECF is indicated. The clearance of low-molecular-weight solutes such as urea is relatively limited.

Solute clearance may be significantly enhanced by having a dialysate solution bathe the blood-filled capillaries running countercurrent to the blood flow, in order to add diffusion to convection. The combination of hemofiltration with dialysis is known as hemodiafiltration. Addition of dialysis also usually suffices to treat supervening acute kidney failure or preexisting chronic kidney failure. Hemodiafiltration, similar to hemodialysis, requires that blood perfuse hollow-fiber dialysis membranes made of synthetic plastics such as polysulfone or polyamide.²⁰ For all of these procedures, the patient usually must be fully anticoagulated, but some hemofilters are available that may not require anticoagulation. Anticoagulation may be achieved either with heparin or with citrate. The hydrostatic pressure required for hemofiltration is derived from a blood pump. Continuous venovenous hemofiltration (CVVH) uses a blood pump to maintain adequate flow rates and has replaced continuous arteriovenous hemofiltration (CAVH), which required arterial puncture with a large-bore catheter. However, the need for a blood pump also necessitates an experienced ICU team to be continuously present for more than the 4 to 6 hours needed for acute hemodialysis or hemoperfusion. Both the expense and the complexity of the xenobiotic-removal procedure are thereby increased. The addition of a dialysate bathing solution to the hemofiltration apparatus changes CVVH, or hemofiltration, to the augmented continuous venovenous hemodialysis (CVVHD), or, with greater convective volumes, hemodiafiltration (CVVHDF) (Fig. 10–2).

Ultrafiltrate flows of 100 to 6000 mL/h across the membrane can be achieved. Fluid and electrolyte losses must be replaced carefully. Depending on the filter, xenobiotics with a molecular weight of up to 40,000 Da, as well as water, urea, creatinine, and sodium, pass into the ultrafiltrate. Heparin, myoglobin, insulin, and vancomycin are examples of larger molecules cleared with relative efficiency.

Attention must be paid to the undesirable removal of therapeutic drugs such as antimicrobials via these continuous modalities. Drug clearances with different synthetic membranes are available in the literature; the doses necessary to maintain therapeutic drug concentrations can also be determined.⁵

Plasmapheresis and Exchange Transfusion

Plasmapheresis and exchange transfusion are intended to eliminate xenobiotics with large molecular weights that are not dialyzable. This includes xenobiotics and endogenous molecules with molecular weights greater than 150,000 Da typified by immunoglobulins. The xenobiotic to be eliminated should also have limited endogenous metabolism to make pheresis or exchange worthwhile.³⁵ By removing plasma proteins, both techniques offer the consequent potential benefit of removal of protein-bound molecules such as Amanita toxins,³⁰ thyroxine, vincristine, monoclonal antibodies, or complexes of digoxin and antidigoxin antibodies. However, there is little evidence that either technique affects the clinical course and prognosis of a patient poisoned by any of these or other xenobiotics.

Pheresis is particularly expensive, and both pheresis and exchange transfusion expose the patient to the risks of infection with plasma- or blood-borne diseases. Replacement of the removed plasma during plasmapheresis can be accomplished with fresh-frozen plasma, albumin, or combinations of both. The former is associated with hypersensitivity reactions, such as fever, urticaria, wheezing, and hypotension, in as many as 21% of cases.³⁵

A different setting in which exchange transfusion may be an appropriate technique is in the management of small infants or neonates in whom dialysis or hemoperfusion may be technically difficult or impossible. Anticoagulation and MDAC may be hazardous and therefore contraindicated in patients in the neonatal nursery, where the risk of intracerebral bleeding and necrotizing enterocolitis is high. In premature neonates, a single volume exchange appeared to alleviate manifestations of theophylline toxicity.⁴⁹ The therapy has been successfully used to treat other pediatric patients with poisonings, including severe salicylism.⁴⁴

OTHER TECHNIQUES TO ENHANCE ELIMINATION

Further discussions of some of the techniques to enhance elimination that are not discussed here may be found in Chap. 31 (exchange transfusion), Special Considerations: SC3 (cerebrospinal fluid drainage and replacement), Chap. 65 (toxin-specific antibodies), and Chap. 96 (chelation). All of these techniques have limited, very specific indications, and the effect of these interventions on the overall body burden of the xenobiotic is usually small.

TOXICOLOGY OF HEMODIALYSIS

Unlike patients who receive acute hemodialysis once or twice in the management of poisoning, patients with chronic kidney failure are repeatedly exposed to large volumes of water derived from municipal reservoirs during the course of their hemodialysis treatments. If an “average” regimen consists of three treatments of 4 hours each week, with dialysate flows of

800 mL/min, patients will be exposed to nearly 600 L of water separated from them only by a semipermeable membrane designed to allow solute passage in either direction. Problems with dialysate generation therefore have the potential to be lethal to this population by exposing them to significant quantities of toxins. There are two potential sources of dialysate contamination: the municipal reservoirs and water treatment plants and the dialysis unit.⁵⁴ The quality of water used for dialysate generation is regulated in the United States by the Association for the Advancement of Medical Instrumentation (AAMI).⁷ This organization regularly revises its guidelines to incorporate new technology and data.

Contamination of dialysate from the municipal water supply may occur as a result of xenobiotic runoff into reservoirs or as a result of inadvertent or intentional addition of a chemical by the municipality. Chlorine and chloramine are frequently added to municipal water supplies to control bacterial populations. However, chlorine may combine with nitrogenous compounds and form chloramine, which may cause nausea, vomiting, methemoglobinemia, and hemolytic anemia.⁷² Recently, chloramine was blamed for decreased bone marrow sensitivity to erythropoietin. Aluminum is present in some municipal water supplies, and before it was recognized as a problem, aluminum led to encephalopathy characterized by seizures, myoclonus, and dementia as well as osteomalacia and microcytic anemia.

Water from the municipal supply entering the dialysis unit is first treated with a water softener to remove calcium and magnesium. It is then run through an activated charcoal bed to adsorb chloramine. The potential toxicity (hemolysis and death) from this compound has caused AAMI to mandate a redundancy in the carbon beds; when the active sites in one carbon bed are exhausted, a second will ensure that no toxicity will occur. Most commonly, water for dialysate is then generated by reverse osmosis, a process that requires that water, in response to applied hydrostatic pressure (and against the osmotic gradient), cross a membrane that is relatively impermeable to solutes, leaving them behind. Alternatively, but less commonly, water can also be purified using deionization, a technique that runs water over an exchange resin, releasing hydroxyl ions in exchange for charged species in the water. Deionization is inferior to reverse osmosis for removal of aluminum and may be associated with release of lethal concentrations of fluoride when exchange sites are exhausted.⁴ General water chemistry testing is mandated annually; testing for chlorine and chloramine must be done before each dialysis shift.

Current requirements are that water be highly purified, but not sterile, because bacteria cannot cross from the dialysate into the blood. However, small quantities of endotoxin (molecular weight, 5–15,000 Da) can cross, particularly in situations that include the use of high-flux membranes. Endotoxin is suspected of contributing to activation of circulating cytokines, malnutrition, fever, and other syndromes such as carpal tunnel syndrome, which are associated with chronic inflammation. Recommendations for the frequency of testing for endotoxin and the maximum amounts of endotoxin tolerated are continually debated and continue to become more stringent. Water distribution systems are cleaned at least monthly with bleach, peracetic acid, or other sterilants. Care must be taken that all of these potential xenobiotics are thoroughly flushed from the system before dialysis is restarted. Other products of bacterial metabolism, such as volatile sulfur-containing compounds, generated on the dialysate side of the membrane may be responsible for symptoms in hemodialysis patients.⁶²

Unusual microbes have also been associated with serious toxicity. Untreated water at one center in Brazil demonstrated growth of Cyanobacteria (blue-green algae) and production of microcystins, cyclic peptides that cause serious hepatic toxicity; patients dialyzed with the contaminated water had a dramatic rate of death from liver failure.³³ Water contamination should especially be suspected when multiple dialysis patients experience similar symptoms nearly simultaneously. Dialysate distribution systems are always made of polyvinyl chloride (PVC) or other inert plastics, rather than copper, which may also leach into the water and cause hemolytic anemia.

Besides water for dialysate, another potential source of poisoning in hemodialysis units is the process of reusing dialysis membranes. Until recently, up to 70% of dialysis units in the United States reused membranes because of cost considerations. Reuse is becoming less common today, in part because the cost of dialyzers has continued to fall. Each dialysis membrane is sterilized with peracetic acid, formaldehyde, or glutaraldehyde. Careful quality assurance programs ensure that there is no significant exposure of the patients to these molecules during the dialysis procedure. Nonetheless, reuse programs are associated with a variety of syndromes such as pyrogenic reactions attributed to patient exposure to germicides or endotoxin caused by inadequate sterilization procedures.⁵⁹ Controversial data over the years have suggested, but not proven, higher mortality rates with reuse. Occupational exposure of dialysis personnel to the relevant sterilants has also been monitored closely.

SUMMARY

- Urinary alkalization and many of the other techniques listed in [Table 10–1](#) can be instituted quickly in the emergency department.
- The extracorporeal methods of xenobiotic removal, including hemodialysis, sorbent hemoperfusion, and continuous hemofiltration, all require consultation with a nephrologist or intensivist.
- Timely use of these techniques requires mobilization of a competent team and preparation of the requisite equipment.
- Rapid identification of a toxic exposure for which these techniques are appropriate and the presence of more ominous

prognostic features should lead to prompt notification of the appropriate consult services so that application of these techniques can proceed in an expeditious manner.

- The applicability of these techniques to new xenobiotics should be considered based on the principles discussed, so that these and newer treatment modalities are not used indiscriminately.
- The literature regarding these techniques in general, and for the treatment of specific xenobiotic exposures in particular, should be read critically and with appropriate skepticism.

11 USE OF THE INTENSIVE CARE UNIT

Kyle B. Enfield and Mark A. Kirk

The practice of critical care medicine has its roots in the resuscitation of dying patients, and it focuses on the restoration of normal physiology without necessarily involving a complete understanding of a patient's chronic conditions. Over the past several decades, critical care has led to improved patient survival from many serious conditions. This is the direct result of noninvasive and invasive tools used to describe and correct pathophysiology.²⁹

Like many critically ill patients, the history of poisoned patients is often partial or incomplete, thereby confounding their care. The history is often unreliable regarding the xenobiotic ingested, time of ingestion, and amount ingested, even further complicating care. Additionally, the xenobiotic may have unknown or unpredictable effects at the exposure dose. Finally, the therapies, antidotes, and complications of acute poisoning may be unfamiliar to the intensive care unit (ICU) staff. These uncertainties challenge health care providers and influence decisions about admitting poisoned patients to the ICU.

In 2011, the American Association of Poison Control Centers (AAPCC) National Poison Database System (NPDS) reported 2,334,004 human exposures, of which 615,869 required health care facility management. Most patients did not require critical care, with only 7% of the total human exposures reporting moderate/major clinical outcomes or death and only 101,175 of the admitted patients admitted to critical care units; this represented only 4.3% of all human exposures reported that year.⁷ Most critically ill poisoned patients have acutely reversible conditions that will clearly benefit from an ICU intervention,⁶⁹ with a total attributable mortality of only 0.06%.

Unlike many patients with diseases managed in the ICU, poisoned patients are often admitted to the ICU for observation and monitoring, not for intervention.⁹³ Fewer than 25% of those hospitalized required specific treatments or antidotes other than gastrointestinal (GI) decontamination.^{6,93} Many physicians elect to observe poisoned patients in an ICU in anticipation of possible delayed, unrecognized life-threatening toxicity. The ICU provides necessary monitoring and individual nursing care that can help in the early recognition of developing toxicity. ICUs give health care providers the best opportunity to minimize morbidity and decrease mortality. However, ICU care is very expensive and has contributed significantly to the escalation of health care costs. In addition, critical care units struggle with overcrowding, requiring a justifiable decision-making process for each and every patient before committing these valuable resource.

The decision to admit a patient to a critical care unit is multifactorial. Patient characteristics, the need for acute reversal of physiologic abnormalities, and the characteristics of the exposure are all potential reasons for admission. Beyond managing the obvious end-organ toxicity requiring intervention, the ICU is especially useful for observing patients for the progression of end-organ effects that may require intervention. Because the natural course of a toxicologic emergency is often unpredictable, consideration must be given to patients at risk of deteriorating to the point that critical care interventions are required. Newer studies are attempting to define predictors of adverse events and risk quantification that will prove helpful in critical care admission decision making.^{23,49,57,88}

Given the degree of uncertainty that is typical for the poisoned patient, an informal "bedside risk assessment" is a helpful tool for decision making. In this case, "bedside risk assessment" is defined as the process of determining the likelihood of physiologic deterioration requiring critical care interventions for an individual after an exposure. This "bedside risk assessment" takes into account observed clinical effects, estimated dose, pharmacologic and toxicologic characteristics of the suspected xenobiotic, and characteristics of the exposed patient to help determine the need for ICU admission. It is intended to identify patients with conditions requiring meticulous supportive care, physiologic monitoring, or advanced technologic or pharmacologic therapies that can only be provided in the ICU. More importantly, it is needed to predict the likelihood of a patient deteriorating to the point of needing critical care interventions. This decision-making guide takes into account key clinical observations, current best available evidence from the medical literature, clinical experience, and preferences based on acceptable risks (Table 11–1).

TABLE 11–1. Key Parameters for Performing a Risk Assessment

Bedside observations for end-organ toxic effects
Evidence-based clinical criteria and severity of illness models
Need for specific monitoring or therapeutic interventions

Xenobiotic characteristics: toxicodynamic and toxicokinetic considerations

Patient factors that increase susceptibility to adverse outcomes

- At-risk populations

- Chronic and other comorbid medical conditions

Risk of life-threatening complications

- Anoxic brain injury

- Aspiration pneumonitis

- Rhabdomyolysis and compartment syndrome

The goal of this chapter is to encourage effective use of ICU resources without compromising patient care by proposing a structured approach to assessing risk. Effective utilization of ICU resources must take into consideration the unique characteristics of a xenobiotic, the capabilities of the hospital, and all realistic alternatives for managing and observing poisoned patients without compromising care. Current medical literature allows for the development of only very general recommendations. Future clinical studies addressing the use of health care resources for poisoned patients will allow refinement of these recommendations and could ultimately lead to clinical guidelines derived from their findings. Although it is impossible to be all inclusive, this chapter provides a risk-assessment strategy for most xenobiotics subsequently discussed in this text.

ASSESSING RISK USING CLINICAL OBSERVATIONS AS THE BASIS FOR ICU ADMISSION

The philosophy of “treating the patient and not the poison” may prove most helpful in the patient’s overall risk assessment. It seems reasonable to assume that a patient’s signs and symptoms can be used to decide the need for ICU admission.

Patients with serious central nervous system (CNS), respiratory, cardiovascular, or metabolic manifestations of poisoning need ICU interventions regardless of the exposure. For example, in a retrospective study⁶ of patients with respiratory failure requiring mechanical ventilation, hypotension or cardiac dysrhythmias requiring cardiovascular resuscitation, recurrent seizures requiring airway management and continuous anticonvulsant therapy, or agitation requiring high-dose sedation all clearly need ICU admission, and they are unlikely to be the subject of clinical research. Regardless of xenobiotic ingested, this study established that a patient’s initial signs and symptoms could be used as criteria to identify poisoned patients at risk of developing serious toxicity, thus needing ICU admission.⁶ Patients were classified as low risk when a set of high-risk clinical criteria were not observed in the emergency department (ED). None of the low-risk patients developed complications or required ICU interventions after admission. All patients developing high-risk complications such as hypoxia, respiratory failure, hypotension, or seizures after admission had other high-risk criteria in the ED.

In this study population, 70% of the low-risk patients were admitted to the ICU for observation. Because none of these patients developed complications or required ICU intervention, the authors postulated that applying their criteria would have eliminated 50% of the ICU days without compromising care. The limitations of this study are multifactorial: retrospective design, relatively small study population, and limited variety of xenobiotic exposures. Additionally, generalizing this study’s conclusions to today’s clinical environment is difficult. This study was published in 1987, and the spectrum of poisoning faced today is vastly different than previously studied. The main message of this study is that with some clinical judgment, many poisoned patients can be effectively triaged. Newer studies suggest that determining high-risk clinical criteria for predicting risk may be useful for triaging patients.^{43,47,48,50}

Patient Characteristics Influencing ICU Admission of Poisoned Patients

In addition to bedside observations, specific populations may be at higher risk for morbidity and mortality secondary to xenobiotic exposures. End-organ toxicity and specific monitoring or therapeutic interventions are the most important reasons to admit poisoned patients to the ICU. However, restricting ICU admission to those with only end-organ toxicity is inappropriate because the ICU is most capable of early recognition of delayed or worsening toxicity, potentially leading to catastrophic deterioration. Minimally symptomatic or asymptomatic patients may require ICU admission because other factors must be considered. In addition to end-organ toxicity, xenobiotic and specific patient characteristics should influence ICU admission decisions.

The patient’s comorbid medical conditions can increase the risk of developing complications related to the ingestion. Many patients who have chronic medical problems do not tolerate major physiologic stressors without significant compromise. For example, a patient with underlying cardiac disease could develop severe myocardial ischemia from a modest carbon monoxide exposure. An elderly or chronically ill or debilitated patient with chronic salicylism is more likely to have major respiratory or CNS complications than a younger, healthier patient. Conditions that alter xenobiotic metabolism or elimination, such as kidney or liver disease, may prolong toxicity or produce toxicity after lesser amounts

are ingested. For many of these reasons, the morbidity and mortality of acute poisoning are higher in elderly patients.⁵⁸

In addition, many toxicologic emergencies occur in young patients who are free of underlying disease. This increases the likelihood of surviving from significant insults such as prolonged hypotension or hypoxia. Indeed, one prospective trial involving 286 patients admitted to the ICU with nontraumatic coma found that 91% of the 101 xenobiotic-induced coma patients survived, a much higher rate than those patients whose cause of coma was hypoxia (33%), sepsis (28%), focal cerebral (26%), or a general cerebral insult (17%).²⁶ Despite negative predictors of outcome, aggressive resuscitation efforts may be justified for poisoned patients. Case reports of poisoning from barbiturates, cyclic antidepressants, baclofen, ethylene glycol, botulism, solvents, and sedative–hypnotics provide specific examples of this observation.^{3,65,80,86,91} Specifically, prolonged cardiac resuscitation should be provided for victims of cardiac arrest resulting from overdoses of cyclic antidepressants, β -adrenergic antagonists, or calcium channel blockers as well as for those with severe hypothermia.^{20,34,54,62,75}

There are situations in which knowledge of the patient's social and psychiatric state may prompt the need for ICU admission as well. For example, patients with physical dependency on ethanol, benzodiazepines, or barbiturates may be admitted to the hospital for acute withdrawal or, during hospitalization, go through a period of abstinence that results in an acute withdrawal syndrome. Withdrawal from ethanol and sedative–hypnotics can have serious consequences and complications. ICU management is frequently indicated because large doses of medications with respiratory depressant effects may be required for treatment. Similarly, the majority of recognized suicide attempts are associated with a psychiatric disorder and/or substance abuse and occur by overdose of medications. Acute complications of poisoning make it difficult to adequately assess suicidal risks. Patients have an increased rate of suicide after discharge from an ICU for drug overdose.⁷⁹ Until suicidal risks are adequately assessed, it must be assumed that overdosed patients need close observation.

Assessing Risk Using Severity of Illness Scoring Systems to Guide ICU Admission

Severity of illness scoring systems are designed to predict survival and length-of-stay using multiple key variables applied at the time of ICU admission or to risk adjust patient mortality based on data collected through the patient's hospitalization.¹⁹ This information helps the bedside clinician and patient's surrogate decision makers determine ICU care choices. These scoring systems serve additional administrative and research roles in comparing patient populations and hospitals.²⁹ It is important to note that these studies have primarily been performed to identify patients at risk for death as opposed to being used as a triage tool; this holds true for the studies presented in this section.

Scoring systems considering physiologic variables prospectively and administrative variables retrospectively are broadly used.¹⁹ Those based on physiologic variables are the most useful to the clinician at the bedside. There are five commonly used scoring systems: the Acute Physiology and Chronic Health Evaluation (APACHE II/III/IV), the Mortality Probability Model (MPM II/III), the Simplified Acute Physiology Score (SAPS II), and the Sequential Organ Failure Assessment (SOFA). For pediatric patients, the Pediatric Risk of Mortality (PRISM II/III) is widely used. All of these models are widely studied and generally accepted severity of illness models that score certain physiologic parameters and other factors to estimate risks and predict outcomes in critically ill individuals.^{14,78}

Clinical studies to validate such scoring systems have included patients with a variety of medical and surgical conditions, although few trials have validated these scoring systems in large cohorts of poisoned patients. The original APACHE II cohort of 5815 ICU admissions from 13 hospitals included only 153 patients admitted to the ICU with a diagnosis of “drug overdose.”³⁸ APACHE II is limited by its failure to distinguish between traumatic and nontraumatic causes of altered mental status, a fact of potentially vital import in cases of overdose. The development of APACHE III addressed this shortcoming of its predecessor. However, even this very complicated scoring system with proprietary mathematical modeling has limited value when applied to a wide range of poisoned patients. In fact, when APACHE III was used by its authors to screen a large independent database of almost 40,000 ICU admissions, including 1032 patients admitted with “drug overdose,” predicted and actual mortality statistics for these patients were vastly different.⁹² Seven deaths (0.7%) were predicted in this cohort, although the actual number turned out to be 25 (2.4%). The difference was statistically significant. APACHE IV has attempted to further address the shortcomings of its predecessor, but it still has relied on parameters collected over the first 24 hours in the ICU.⁷⁸ Additional articles addressing the usage of severity of illness scoring systems to identify high-risk overdose patients are lacking, although one review of 216 consecutive ICU admissions for intentional overdose found that admission APACHE II and Glasgow Coma Scale (GCS) were equally strong predictors of morbidity and mortality.³⁰ Specifically, a GCS of 12 or less was 88% sensitive and 92% specific in identifying patients at risk for developing morbidity requiring ICU admission. A recently published consortium study of 2755 poisoned patients admitted to an ICU in Finland predictably showed that the nonsurvivors had higher APACHE II and SOFA scores than survivors (APACHE II 27.2 versus 14.1 and SOFA 9.0 versus 4.7; $P < 0.001$). In multivariate regression, respiratory failure, kidney failure, and hypotension were key abnormalities that predicted prolonged ICU care and mortality.⁴⁴ A prospective study in 92 mixed ingestions presenting with coma showed that APACHE II, MAS (Modified APACHE II), and GCS all performed reasonably well in terms of discriminating survivors from nonsurvivors,

both at presentation and at 24 hours.¹⁷

Given the unique characteristics of individual xenobiotics, other authors have attempted to apply severity of illness models in specific instances. Within 24 hours of presentation, both SOFA and APACHE II scores showed promise as predictors of mortality when studied prospectively in acetaminophen (APAP)-induced acute liver failure, revealing similar power to predict a poor outcome when compared against the widely accepted King's College Criteria.^{11,56} Two studies evaluating organic phosphorus compound poisoning used APACHE II and SAPS II scores demonstrated that high scores were predictive of mortality.^{42,73} However, some clinical outcome predictors used in these scoring systems, such as neurologic outcome after cardiac arrest, are unreliable in poisoned patients.¹⁸ Patients with severe poisoning may have clinical characteristics that mimic brain death yet have a complete neurologic recovery.

Results of severity of illness models must be cautiously used.⁷⁸ These models lack individual prognostic application, and decisions about individual patients still require clinical judgment. Scores for these models need to be validated for the specific population for which they are to be used. A specific limitation of these models is lead-time bias (ie, pre-ICU care that influences mortality and in which the sole outcome measure is mortality). Additionally, some of these models use the most extreme values at 24 or 48 hours, and so when used at admission, they may underrepresent the patients' true predicted mortality.¹⁹ Therefore, severity of illness models to guide ICU care must be used cautiously when applied specifically to poisoned patients. More study is needed before any severity of illness model can be considered reliable in predicting which patients are at the highest risk of developing ICU-requiring morbidity or mortality.

Beyond illness scoring system literature, few studies specifically evaluate the use of the ICU for poisoned patients.^{6,27,31,33,39,79,83} Prospective studies focus on mortality rates, use of resources, or types of xenobiotics ingested; other studies, mostly retrospective ones, focus on patients exposed to a specific xenobiotic. Taken together, this suggests that physiologic risk assessment may be helpful to clinicians as an adjunct to other clinical factors and is an area where "triage" studies would provide the most useful new insight. Initiatives in the United States (American College of Medical Toxicology's Toxicology Investigators Consortium {ToxIC} and in Australia) have begun creating registries of patients directly treated by practicing medical toxicologists. These registries promise to capture high-quality clinical data that can advance our understanding of risk and potentially guide future clinical guideline development.^{85,87}

Ideally, clinical indicators for ICU care could be established for each xenobiotic, but these would be limited based on the uncertainty associated with the patient's presentation. Universal criteria cannot be applied to all poisoned patients because of the unique clinical course of some xenobiotics and the uncertainty regarding which xenobiotics were ingested. In one outcome study of elderly poisoned patients, the authors observed that each category of poisoning has its own special risk profile.⁵⁸ Until more specific predictors of outcome are developed for individual xenobiotics, nothing will be more useful than experience and good clinical judgment in predicting who may benefit from ICU admission. At present, withholding ICU care from poisoned patients based solely on a nonspecific "score" will not result in significant cost savings in the ICU but may increase the risk of morbidity and mortality.

Assessing Risk Using Xenobiotic Characteristics as a Basis for ICU Admission

Both the known and unknown characteristics of a xenobiotic will assist with ICU admission decisions. Some xenobiotics have proven their capability to cause harm or death to humans. Well-described, expected toxic effects assist in early recognition of poisoning. For other xenobiotics, the consequences after exposure are not yet reported.

ICU admission is warranted for patients with expected serious toxic effects from a xenobiotic. This is especially true for xenobiotics known to be deadly, such as calcium channel blockers, cyanide, cyclic antidepressants, and salicylates. For example, patients with calcium channel blocker poisoning who exhibit hemodynamic compromise require close attention and meticulous continuous treatment available only in critical care units.

Due to the availability of newer antidepressants in the past few years, poisoning from cyclic antidepressants is less common. However, the literature attempting to identify the clinical indicators of serious toxicity serves as an excellent case study. Indicators of toxicity should be identified for individual xenobiotics so that high-risk patients may be closely monitored and aggressively treated. Patients who have ingested cyclic antidepressants develop substantial morbidity and mortality and have been studied in great detail to determine indicators of toxicity. These studies demonstrate that a prolonged QRS complex on a 12-lead electrocardiogram (ECG) is predictive of serious complications such as seizures and dysrhythmias.^{4,60} Any patient manifesting ECG abnormalities (including QRS ≥ 0.10 seconds) or hypotension requires ICU monitoring.⁹ Unlike cyclic antidepressants, most xenobiotics do not have such an extensive literature to define high-risk patients.

Xenobiotics inducing liver injury have received some of the greatest attention in determining risk based on the known characteristics of the ingestion. For example, most APAP-poisoned patients can be safely managed outside of the ICU because they exhibit no end-organ toxicity and their hospital management entails only laboratory monitoring and antidotal therapy with N-acetylcysteine. However, APAP poisoning can be lethal, and at some point in the clinical course, manifestations of toxicity require close monitoring and treatments available only in the ICU. Predictors of poor outcome have been studied and can be useful guides for selecting patients who need ICU care. The King's College Criteria are well-

established indicators of impending hepatic failure and the need for evaluation for possible transplantation. Patients with abnormal clinical and laboratory data approaching these criteria are candidates for ICU admission or transfer to a specialized center with advanced ICU resources and transplantation services.⁶¹ In addition, the use of the discriminate function in risk adjusting for acute alcoholic hepatitis uses the patient's total bilirubin and prothrombin time. It has been used to predict severity, mortality, and indications for treatment following acute ingestion of alcohol.^{45,59,67}

Decisions can be challenging when the characteristics and clinical course of the xenobiotic are unknown. New pharmaceutical and industrial products are introduced every year with little data on toxic exposure doses or human health effects in overdose. Sometimes animal studies provide the only known toxicologic data, and preclinical trials for new xenobiotics may have excluded the populations at risk, such as infants, children, or the elderly. In these cases, clinicians must often make therapeutic decisions and anticipate potential toxicity with little or no reliable data. Because early recognition of serious toxicity may prevent an adverse outcome, expectant observation may be the only rational approach. For example, intentional and unintentional ingestions followed the introduction of fluoxetine. Because, at that time, clinicians lacked experience treating overdoses of this xenobiotic and had no data regarding the natural course and toxic dose, many patients were admitted to the ICU for observation of toxic effects. Now that clinicians have experience with this drug and studies are available demonstrating few severe manifestations, ICU resources are seldom needed to treat such patients.^{5,77}

Failure to appreciate the potential for serious, delayed toxic effects is a major pitfall in managing poisoned patients. An asymptomatic patient may be a "time bomb" with the potential to deteriorate rapidly. Delayed or continued absorption, slow tissue distribution, interference with cellular function, production of toxic metabolites, or depletion of target organ reserve capacity are causes of delayed onset of clinical effects.

Certain xenobiotics prolong GI absorption, delaying onset of toxicity.⁵³ Sustained-release pharmaceutical preparations and those with enteric coatings enhance patient compliance but, in overdose, may delay absorption and, in turn, make the onset of toxicity unpredictable.⁵⁵ Published cases of overdoses with sustained-release verapamil, diltiazem, and bupropion as well as long-acting opioids and enteric-coated aspirin report delayed onset of toxicity (>6 hours), with peak serum concentrations measured more than 24 hours after ingestion.^{21,76,90}

Serial xenobiotic concentrations are necessary to verify peaks and ensure decreasing concentrations. Serial concentrations may, if available, warn of increasing potential for serious toxic effects. However, when serum concentrations are unobtainable, extended observation, possibly in the ICU, is required for many patients with overdoses of sustained-release and enteric-coated medications.

Clinical effects may be delayed when toxicity depends on alteration of enzyme functions, cellular reproduction, or metabolic function. For example, toxicity from colchicine may not be apparent for many hours after an overdose but then may progress rapidly to severe toxicity such as cardiovascular collapse. Other xenobiotics may take days to exhibit their toxic effects. For example, methotrexate and other chemotherapeutics may cause life-threatening bone marrow suppression days after exposure. When there is potential for serious delayed toxicity, prolonged close patient monitoring, typically in an ICU setting, is necessary.

PHYSIOLOGIC MONITORING AND SPECIALIZED TREATMENT AS REQUIREMENTS FOR ICU ADMISSION

The medical toxicologist, prepared with a thorough understanding of pharmacokinetics, pharmacodynamics, and unique treatments for poisoning, can collaborate with the critical care specialist to optimize physiologic function. This combination provides the patient the greatest opportunity for a good clinical outcome.

One benefit of the ICU for the poisoned patient is the ability to rapidly respond to failing vital organs and to titrate therapies to restore normal physiology in the critically ill. This is achieved through a nurse-to-patient ratio that allows for frequent or continuous monitoring of basic physiologic parameters. These measurements of vital signs, neurologic status, and fluid intake and output measurements, along with continuous cardiac monitoring, make possible early detection of toxicity, recognition of conditions needing active intervention, and prevention of complications.²⁹ Medical technologic advances now provide a number of invasive and noninvasive capabilities that can signal or offer trends indicating risk of catastrophic deterioration or feedback on response to therapy.⁶⁴ For example, monitoring hemodynamic parameters are valuable for managing poisoned patients with hypotension, intravascular volume depletion, or respiratory failure from acute respiratory distress syndrome (ARDS). Most importantly, clinicians must recognize that no monitoring device improves clinical outcome unless coupled with a treatment that improves outcome.²⁸

Most critically ill poisoned patients have acute reversible conditions requiring supportive care measures (ie, ventilator support, vasopressor support, or both) and close monitoring that only ICUs are equipped to provide. Most often, supportive care measures improve the outcome of critically ill poisoned patients more than antidotes and specialized treatments. Focus on supportive care measures, such as maintaining a patent airway, preventing hypoxia with the administration of oxygen, and treatment of shock, decreased the mortality for patients with barbiturate overdoses from 20% in the 1930s to less than

2% in the 1950s.¹³ This approach seems equally important in this century to achieve desired patient outcomes in the critically ill. Studies in both adults and children report good outcomes in most critically ill poisoned patients treated with only mechanical ventilation, vasopressor support, and careful monitoring.^{18,39}

Many antidotes and specific treatments should be administered in the ED and the ICU settings. Although these treatments may possibly be life saving, they may have inherent risks. Because these treatments may be unfamiliar to staff, the ICU is the most appropriate environment to administer or continue such treatments. Whereas some antidotes are administered in unconventional doses, other familiar drugs should be avoided in treating patients with toxicologic emergencies. In toxicologic emergencies, a familiar drug may be an antidotal therapy that requires doses that far exceed conventional regimens or indications that deviate from common treatment protocols. High doses of atropine (ie, hundreds of milligrams) may be necessary for the treatment of patients with organic phosphorus insecticide poisoning.^{15,25,41} Vasopressors that are commonly used in medical hypotension, such as sepsis, should be avoided in most cases of xenobiotic-induced hypotension until specific antidotal therapy fails.

A false sense of security can result when an antidote reverses toxicity but has a shorter duration of effect than the xenobiotic. An example is a patient, comatose from an opioid overdose who responds to naloxone, awakens, and refuses further treatment. Sedation and possibly respiratory depression may reappear when the short duration of effect of naloxone allows opioid toxicity to recur. These patients must be closely observed for the possible need to readminister the antidote. In a retrospective review of patients presenting with opioid overdosage, 31% of 84 naloxone responders experienced resedation necessitating readministration.⁸⁴ Resedation is particularly problematic with long-acting opioids such as methadone and controlled-release preparations of oxycodone and morphine.³²

Extracorporeal methods of eliminating xenobiotics, such as hemodialysis and continuous venovenous hemofiltration, are ideally performed in the ICU.²² Invasive procedures, such as extracorporeal membrane oxygenation, cardiopulmonary bypass, and intraaortic balloon pump-assisted perfusion, are used successfully in resuscitating critically ill poisoned patients.^{34,40,74}

When the need for surgical intervention or specialized wound care is anticipated, patients with toxicologic emergencies are ideally managed in the ICU. Although transplantation becomes necessary in a minority of critically ill APAP-poisoned patients, this treatment can improve survival to discharge by as much as 75%.² Compartment syndrome, from muscle compression after prolonged xenobiotic-induced coma, is a rare but limb-threatening occurrence that sometimes results in the need for fasciotomy.²⁴ Any poisoned patient with significant rhabdomyolysis, whether localized or more widespread, is at risk for the development of compartment syndrome and acute kidney failure. If contemplating fasciotomy, monitoring and specialized postoperative care in an ICU is warranted. Plasmapheresis and specialized wound care in an ICU are necessary in cases of toxic epidermal necrolysis (TEN) secondary to xenobiotics. Mortality and morbidity may be reduced by early referral to a specialized burn center for conditions such as TEN or significant dermal burns from caustics.

LIFE-THREATENING COMPLICATIONS ASSOCIATED WITH POISONING

Poisoning produces both anticipated and unanticipated complications that can prolong ICU care and decrease survival. Serious complications of poisoning include pulmonary compromise, rhabdomyolysis, compartment syndrome, and anoxic brain injury. Complications such as acute kidney or liver failure also might prolong an ICU course.

Pulmonary compromise after toxic exposures often develops after several hours or days in the ICU. Pulmonary complications after a toxic exposure include aspiration pneumonitis and ARDS, leading to prolonged ICU stays, higher mortality, and substantial additional medical costs.⁶⁶ Aspiration of gastric contents is an uncommon but serious complication of poisoning, especially when a patient's mental status is altered and protective airway reflexes are lost.^{12,36} Poisoned patients may aspirate spontaneously while lying unresponsive before being discovered, from stomach dilation secondary to bag–valve–mask ventilation, from GI decontamination procedures such as orogastric lavage, or during insertion of endotracheal or nasogastric tubes.^{12,36} In a review of 4562 poisoning admissions, 71 patients clearly had aspiration pneumonitis, yielding a rate of 1.6%.³⁶ In logistic regression analysis, older age, a GCS below 15, spontaneous emesis, delayed presentation to the hospital, and ingestion of cyclic antidepressants were associated with aspiration pneumonitis. Not only were the rates of ICU admission and length of stay increased in the patients with aspiration pneumonitis, but mortality was also higher, with a rate of 8.5% compared with 0.4% for those without.

Poisoning may cause global cerebral anoxia from prolonged shock, respiratory failure, or direct toxic metabolic effects. Distinguishing anoxic cerebral injury from reversible encephalopathy can be difficult in poisoned patients. Coma and loss of brainstem reflexes after prolonged, severe cerebral hypoxia indicate a poor prognosis.^{80,89} Ancillary tests such as electroencephalography (EEG), computed tomography, cerebral angiography, magnetic resonance, and nuclear brain flow studies may be useful in assessing cerebral function and structural integrity. Results should be interpreted with caution when attempting to confirm brain death following drug overdose. EEG can be particularly misleading in certain overdoses, such as those involving benzodiazepines, barbiturates, or baclofen in which the lack of electrical brain activity is a direct effect of the xenobiotic.⁸⁰ Angiographic imaging via CT or direct arteriography may prove particularly useful in such cases,

although such tests can reveal continued blood flow when intracranial hypertension is absent despite severe axonal injury and brain death.⁵² Because clinical predictors of outcome may be unreliable when applied to poisoned patients, the diagnosis of brain death should be made cautiously. Cerebral edema is often a secondary effect of global cerebral anoxia, although some xenobiotics have direct cellular effects. Cerebral edema can be a complication of APAP-induced fulminant hepatic failure and the result of direct neuronal injury from salicylate and lead poisoning.^{51,68,81} Rigorous ICU care is preferred to treat patients with xenobiotic-induced cerebral injuries.

ALTERNATIVES TO ICU ADMISSION

Placing patients in the ICU solely for observation often is an ineffective use of this expensive resource. Patient placement decisions require balancing necessary health care resources with risk of adverse patient events. Until further clinical studies are available to define patients who are at risk for serious toxicity or life-threatening complications, many poisoned patients will be admitted to the ICU for observation. When information about the xenobiotic, the patient, and the capabilities of the medical unit are all considered, many patients can be safely observed outside the ICU. [Table 11–2](#) presents some items to consider when making disposition decisions.

TABLE 11–2. Considerations for Intensive Care Unit Admission

<i>Patient Characteristics</i>	<i>Xenobiotic Characteristics</i>	<i>Capabilities of the Inpatient/Observation Unit</i>
Does the patient have any signs of serious end-organ toxicity?	Are there known serious sequelae (eg, cyclic antidepressants, calcium channel blockers)?	Does the admitting health care team appreciate the potential seriousness of a toxicologic emergency?
Are the end-organ effects progressing?	Can the patient deteriorate rapidly from its toxic effects?	Is the nursing staff:
Are laboratory data suggestive of serious toxicity?	Is the onset of toxicity likely to be delayed (eg, sustained-release preparation, slowed GI motility, or delayed toxic effects)?	Familiar with this toxicologic emergency?
Is the patient a high risk for complications requiring ICU intervention?	Does the xenobiotic have effects that will require cardiac monitoring?	Familiar with the potential for serious complications?
Seizures	Is the amount ingested a potentially serious or potentially lethal dose?	Is the staffing adequate to monitor the patient?
Unresponsive to verbal stimuli	Are xenobiotic concentrations rising?	What is the ratio of nurses to patients?
Level of consciousness impaired to the point of potential airway compromise	Is the required or planned therapy unconventional (eg, large doses of atropine for treating overdoses of organic phosphorus insecticides)?	Are time-consuming nursing activities required and realistic?
PCO ₂ >45 mm Hg	Does the therapy have potentially serious adverse effects?	Can a safe environment be provided for a suicidal patient?
Systolic blood pressure <80 mm Hg (in an adult)	Is there insufficient literature to describe the potential human toxic effects?	Can a patient have suicide precautions and monitoring with a medical floor bed?
Cardiac dysrhythmias (ventricular dysrhythmias, high-grade conduction abnormalities)	Are potentially serious coingestants likely (must take into account the reliability of the history)?	Can a one-to-one observer be present in the room with the patient?
Abnormal ECG complexes and intervals (QRS duration ≥0.10 seconds; QT prolongation)		Can the patient be restrained?
Is the patient at high risk for complications such as aspiration pneumonia, anoxic brain injury, rhabdomyolysis, or compartment syndrome?		
Does the patient have preexisting medical conditions that could predispose to complications?		
Alcohol or drug dependence		
Liver disease		
Acute kidney injury or chronic kidney disease		
Heart disease		
Pregnancy: is the xenobiotic or the antidote teratogenic?		
Is the patient suicidal?		

Alternatives to ICU admission include an adult medical or pediatric floor bed, an intermediate care unit, a telemetry-monitored bed, a medical psychiatric unit, a hospital short stay unit, or an ED observation unit. Capabilities for managing poisoned patients may vary considerably between institutions and in different types of patient care areas. It is essential to understand the capabilities of the unit where a patient is being considered for admission. If the nursing staff is unfamiliar with the potential for rapid deterioration of the patient or the staffing pattern does not allow for close observation, the patient outcome can be severely compromised. For example, it is unrealistic to expect a nurse to perform/record frequent vital signs, make serial neuropsychiatric evaluations, and maintain a close watch for respiratory depression in a patient with altered mental status while caring for other patients.

ED observation may be an alternative for the care of select poisoned patients.^{8,35,70,71} An observation unit is dedicated

space, frequently located near the ED, providing focused care and observation to patients needing less than 24 hours of additional care but not yet ready to safely leave the hospital. Data projections suggest that using ED observation units saves significant dollars for the health care system.¹ These units are capable of frequent monitoring of vital signs, continuous cardiac monitoring, and maintaining a safe environment for suicidal patients.^{70,82} Patients with a low risk of serious toxicity or life-threatening complications who require only observation may be ideal candidates for ED observation units.

Many poisoned patients are placed in the ICU because they are suicide risks. Institutions differ on monitoring policies for suicidal patients not admitted on a psychiatric unit. Other than the ICU, many hospitals cannot provide an alternative for observing high-risk suicidal patients because one-on-one monitoring is cost prohibitive. Less costly alternatives are available, but they must ensure a safe environment for suicidal patients. An ED observation unit, an intermediate care unit, a medical psychiatric unit, or a one-on-one observer can safely monitor these patients.

Future studies must further define prognostic factors for poisoning complications. Patients can then be stratified into high- or low-risk groups. The limitations of current studies prevent generalizing the results to individual patients or certain subgroups. Unfortunately, many current policies now being used to regulate admission decisions to the ICU are clinical practice guidelines unlikely derived from the best and most recent evidence. Clinical guidelines should be based on sound evidence so they optimize the use of resources and minimize the risk of harm to patients.

CRITERIA FOR SAFE TRANSFER OUT OF THE ICU

After the acute toxic effects have resolved, most patients are safe to transfer out of the ICU. A good example for establishing safe criteria comes from past experiences with cyclic antidepressant overdoses. These patients were studied to determine when it was safe to discontinue monitoring. Concerns arose from case reports of patients developing sudden death as late as several days after a cyclic antidepressant overdose.^{9,53,72} In most cases, delayed complications developed in the setting of continued toxicity evidenced by lethargy or sinus tachycardia. Several subsequent studies demonstrate that dysrhythmias do not occur after signs of toxicity have resolved (ie, CNS and cardiac manifestations).^{10,63} The authors of these studies suggested cardiac monitoring for an additional 24 hours after normalization of the ECG and resolution of other signs of continued toxicity such as normalization of the mental status and blood pressure.¹⁰ This additional period of monitoring should occur after discontinuation of all specific forms of therapy, such as serum alkalization.

Most xenobiotics have not received the level of attention given to cyclic antidepressants, making clinical judgments the only basis for deciding when to discharge a patient from the ICU, pending further research and experience. For example, drug-induced QT interval prolongation may increase the risk of developing torsade de pointes.³⁷

Ongoing risk of complications or delayed deterioration may be pitfalls to a patient's safe discharge from an ICU. It is necessary to carefully consider discharge decisions about patients exposed to xenobiotics, such as colchicine, with serious delayed clinical effects. Clinicians should also be mindful that the duration of action of the xenobiotic may be longer than the duration of action of the specific treatment or antidote.

Finally, the patient's suicidal intent must be considered before transfer to a less closely monitored hospital unit. Transfer out of the ICU should occur only after assessment of suicide risk and other important psychosocial issues. Early involvement of psychiatric services, chemical dependency counseling, and social services can expedite ICU disposition. Disposition and treatment options may be considered at a time when the patient is still medically unstable by interviewing his or her family, friends, and outpatient counselors.

ICU-to-ICU Transfer

Poisoned patients may require ICU-to-ICU transfer in order to meet their critical care needs, but this poses a risk to the patient. Poison centers and medical toxicologists play a significant role in identifying clinical parameters that alert to impending deterioration, provide therapeutic advice to stabilize the patient until transferred, and can often facilitate rapid transfer to a higher level care facility with specialized capabilities. Although the etiology is not fully understood, there is an association between increasing mortality and distance traveled, medical complications, severity of illness, and subtype of illness.¹⁶ At one academic medical center, use of a structured instrument to guide communication between a transferring and a receiving ICU reduced the adjusted mortality. This suggests that individuals responsible for accepting patients for transfer should develop tools to systematize their process. In this study, one unique finding was the identification of three APAP overdoses who were not on N-acetylcysteine therapy at the transferring institution.⁴⁶

FUTURE DIRECTIONS

All of the health care components supporting patient care form a complex system facilitating the movement of the patient through the system, exchanging information, making critical decisions to optimize care, and aligning the necessary resources to treat critically ill poisoned patients. This complex system contains leverage points composed of those places where interventions may significantly influence patient outcomes and appropriately focus resources. To most influence the care of

future critically ill poisoned patients, the medical toxicologist should focus on studying this complex system, uncovering its leverage points and endeavoring to optimize it in as many directions as possible.

The medical toxicologist can enhance the care of critically ill poisoned patients by rapidly recognizing those patients most at risk for critical illness and finding those benefiting most from early specialized interventions. Additionally, the medical toxicologist augments the critical care specialist's ability to restore normal physiology to critically ill poisoned patients by sharing expert knowledge of early indicators of potentially severe toxicity and in-depth understanding of pharmacodynamics, pharmacokinetics, and specialized treatments.

Clearly identified clinical parameters, serving as clues or patterns predicting high risk for serious toxicity, can function as early warning detectors, decreasing reaction times to those critical actions that most benefit patient outcomes. Research discovering these key parameters could optimize this entire complex system supporting the care of critically ill poisoned patients. These patients have a much better chance of a positive outcome when clinicians define parameters which will inform them sufficiently quickly to recognize impending harmful consequences and leading to interventions that prevent or lessen harm. Such parameters allow poison centers and medical toxicologists to facilitate rapid transfer to a higher level care facility with specialized capabilities. With these parameters, physicians can select candidates for the ICU who are at highest risk of impending harm and can confidently and safely transfer those lower risk patients to alternative care sites outside of the ICU. Within the ICU, these parameters allow early recognition of impending deterioration, leading to interventions optimizing physiology, lessening harm, and preventing complications. Finally, they assist clinicians' ability to recognize the timing for a safe transfer from ICU care, streamlining the flow of patients for optimum use of these valuable resources.

SUMMARY

- Acute poisoning challenges the medical and nursing staff because of its unpredictable clinical course and unfamiliar therapies.
- Poisoned patients are especially problematic because their clinical history is incomplete and the medical literature is often limited. These potential unknowns create many uncertainties in management.
- Because the ICU offers the highest level of skilled staff and modern technology available, most seriously poisoned patients should be admitted there.
- Whether this is clinically justified or is an effective use of resources for a given patient remains a debated issue because admission of poisoned patients continues to be based mostly on clinical judgment and the best available information.

PART B

THE FUNDAMENTAL PRINCIPLES OF MEDICAL
TOXICOLOGY

SECTION I

BIOCHEMICAL AND MOLECULAR BASIS

12 CHEMICAL PRINCIPLES

Stephen J. Traub and Lewis S. Nelson

Chemistry is the science of matter; it encompasses the structure, physical properties, and reactivities of atoms and their compounds. In many respects, toxicology is the science of the interactions of matter with living entities. Chemistry and toxicology are therefore intimately linked. The study of the principles of inorganic, organic, and biologic chemistry offers important insight into the mechanisms and clinical manifestations of xenobiotics and poisoning. This chapter reviews many of these tenets and provides relevance to the current practice of medical toxicology.

THE STRUCTURE OF MATTER

Basic Structure

Matter includes the substances of which everything is made. Elements are the foundation of matter, and all matter is made from one or more of the known elements. An atom is the smallest quantity of a given element that retains the properties of that element. Atoms consist of a nucleus, incorporating protons and neutrons, coupled with its orbiting electrons. The atomic number is the number of protons in the nucleus of an atom, and it is a whole number that is unique for each element. Thus, elements with 6 protons are always carbon, and all forms of carbon have exactly 6 protons. However, although the vast majority of carbon nuclei have 6 neutrons in addition to the protons, accounting for an atomic mass (protons plus neutrons) of 12 (^{12}C), a small proportion of naturally occurring carbon nuclei, called isotopes, have 8 neutrons and a mass number of (^{14}C). This is the reason that the atomic weight of carbon displayed on the periodic table is 12.011, and not 12, as it actually represents the average atomic masses of all isotopes found in nature weighted by their frequency of occurrence. Moreover, ^{14}C is actually a radioisotope, which is an isotope with an unstable nucleus that emits radiation (particles or rays) until it achieves a stable state ([Chap. 134](#)). The atomic weight, measured in grams per mole (g/mol), also indicates the molar mass of the element. That is, in one atomic weight (12.011 g for carbon) there is one mole (6.023×10^{23}) of atoms.

Elements combine chemically to form compounds, which generally have physical and chemical properties that differ from those of the constituent elements. The elements in a compound can be separated only by chemical means that destroy the original compound, as occurs during the burning (ie, oxidation) of a hydrocarbon, a process that releases the carbon principally as carbon dioxide and the hydrogen principally as water (H_2O). This important property differentiates compounds from mixtures, which are combinations of elements or compounds that can be separated by physical means such as the distillation of petroleum into its hydrocarbon components or the evaporation of seawater to separate water from sodium chloride and other substances. With notable exceptions, such as the elemental forms of many metals or halogens (eg, Cl_2), most xenobiotics are compounds or mixtures.

Dimitri Mendeleev, a Russian chemist in the mid-19th century, recognized that when all of the known elements were arranged in order of atomic weight, certain patterns of reactivity became apparent. The result of his work was the Periodic Table of the Elements ([Fig. 12-1](#)), which, with some minor alterations, is still an essential tool today. All of the currently recognized elements are represented; those heavier than uranium are known not to occur in nature. Many of the symbols used to identify the elements refer to the Latin name of the element. For example, silver is Ag, for argentum, and mercury is Hg, for hydrargyrum, literally “silver water.”

FIGURE 12–1. The Periodic Table of the Elements.

The reason for the periodicity of the table relates to the electrons that circle the nucleus in discrete orbitals. Although the details of quantum mechanics and electronic configuration are complex, it is important to review some aspects in order to predict chemical reactivity. Orbitals, or quantum shells, represent the energy levels in which electrons may exist around the nucleus. The orbitals are identified by various schemes, but the maximum number of electrons each orbital may contain is calculated as $2x^2$, where x represents the numerical rank order of the orbital. Thus, the first orbital may contain 2 electrons, the second orbital may contain 8, the third may contain 18, and so on. However, the outermost shell (designated by s, p, d nomenclature) of each orbital may only contain up to 8 electrons. This is irrelevant through element 20, calcium, because there is no need to fill the third-level or d shells. Even though the third orbital may contain 18 electrons, once 8 are present the 4s electrons dip below the 3d electrons in energy and this shell begins to fill. This occurs at element 21, scandium, and accounts for its chemical properties and those of the other transition elements. Transition elements are chemically defined as elements that form at least one ion with a partially filled subshell of d electrons. Also, because the inert gas elements, which are also known as noble gases, have complete outermost orbitals, they are unreactive under standard conditions.

In general, only electrons in unfilled shells, or valence shells, are involved in chemical reactions. This property relates to the fact that the most stable form of an element occurs when the configuration of its valence shell resembles that of the nearest noble gas, found in group 0 on the periodic table. This state can be obtained through the gaining, losing, or sharing of electrons with other elements and is the basis for virtually all chemical reactions.

INORGANIC CHEMISTRY

The Periodic Table

Chemical Reactivity. Broadly, the periodic table is divided into metals and nonmetals. Metals, in their elemental form, are typically malleable solids that conduct electricity, whereas nonmetals are usually dull, fragile, nonconductive compounds (C, N, P, O, S, Se, halogens). The metals are found on the left side of the periodic table, and account for the majority of the elements, whereas the nonmetals are on the right side. Separating the two groups are the metalloids, which fall on a jagged line starting with boron (B, Si, Ge, As, Sb, Te, At). Metalloids have chemical properties that are intermediate between the metals and the nonmetals. Each column of elements is termed a family or group, and each row is a period. Although conceived and organized in periods, trends in the chemical reactivity, and therefore toxicity, typically exist within the groups.

The ability of any particular element to produce toxicologic effects relates directly to one or more of its many physicochemical properties. These properties may, to some extent, be predicted by their location on the periodic table. For example, arsenate may substitute for phosphate in the mitochondrial production of adenosine triphosphate (ATP), creating adenosine diphosphate monoarsenate ([Chap. 13](#)). Because this compound is unstable and not useful as an energy source, energy production by the cell fails; in this manner arsenic interferes with oxidative phosphorylation. The existence of an interrelationship between Ca^{2+} and either Mg^{2+} or Ba^{2+} is predictable, although the actual effects are not. Under most circumstances Mg^{2+} is a Ca^{2+} antagonist, and patients with hypermagnesemia present with neuromuscular weakness caused by blockade of myocyte calcium channels. Alternatively, Ba^{2+} mimics Ca^{2+} and closes Ca^{2+} -dependent K^+ channels in myocytes, producing life-threatening hypokalemia. The physiologic relationships among the ions of lithium (Li^+), potassium (K^+), and sodium (Na^+) are also consistent with their chemical similarities (all alkali metals in Group IA). However, the clinical similarity between thallium (thallous) ion (Tl^+) and K^+ is not immediately predictable. Other than their monovalent nature (ie, +1 charge), it is difficult to predict the substitution of Tl^+ (Group IIIA, Period 6) for K^+ (Group IA, Period 4) in membrane ion channel functions, until the similarity of their ionic radii is known (Tl^+ , 1.47 Å; K^+ , 1.33 Å).

Alkali and Alkaline Earth Metals. Alkali metals (Group IA: Li, Na, K, Rb, Cs, Fr) and hydrogen (not an alkali metal on earth) have a single outer valence electron and lose this electron easily to form compounds with a valence of 1+. The alkaline earth metals (Group IIA: Be, Mg, Ca, Sr, Ba, Ra) (between the alkali and rare earth, Group IIIB) readily lose two electrons, and their cations have a 2+ charge. In their metallic form, members of both of these groups react violently with water to liberate strongly basic solutions accounting for their group names ($2\text{Na}^0 + 2\text{H}_2\text{O} \rightarrow 2\text{NaOH} + \text{H}_2$). The soluble ionic forms of sodium, potassium, or calcium, which are critical to survival, also produce life-threatening symptoms following excessive intake ([Chap. 19](#)). Xenobiotics may interfere with the physiologic role of these key electrolytes. Li^+ may mimic K^+ and enter neurons through K^+ channels, where it then serves as an inadequate substrate for the repolarizing of Na^+ - K^+ -ATPase. Thus, Li^+ interferes with cellular K^+ homeostasis and alters neuronal repolarization accounting for the neuroexcitability manifesting as tremor. Similarly, as noted previously, the molecular effects of Mg^{2+} and Ba^{2+} may supplant those of Ca^{2+} . More commonly, though, the consequential toxicities ascribed to alkali or alkaline earth salts actually relate to the anionic component. In the case of NaOH or $\text{Ca}(\text{OH})_2$, it is the hydroxide anion (not the hydroxyl

radical), while it is the CN^- anion in patients poisoned with potassium cyanide (KCN).

Transition Metals. Unlike the alkali and alkaline earth metals, most other metallic elements are neither soluble nor reactive. This includes the transition metals (Group IB to VIIIB), a large group that contains several ubiquitous metals such as iron (Fe) and copper (Cu). These elements, in their metallic form, are widely used in both industrial and household applications because of their high tensile strength, density, and melting point, which is partly a result of their ability to delocalize the electrons in the d orbital throughout the metallic lattice. Transition metals also form brightly colored salts that find widespread applications, including as pigments for paints or fireworks. The ionic forms, unlike the metallic forms, of these elements are typically highly reactive and toxicologically important. Chemically, the transition elements are elements that form at least one ion with a partially filled subshell of d electrons. Because the transition metals have partially filled valence shells, they are capable of obtaining several, usually positive, oxidation states. This important mechanism explains the role of transition metals in redox reactions generally as electron acceptors (see Reduction-Oxidation below). This reactivity is used by organisms in various physiologic, catalytic, and coordination roles, such as at the active sites of enzymes and in hemoglobin, respectively. As expected, the substantial reactivity of these transition metal elements is associated with cellular injury caused by several mechanisms, including the generation of reactive oxygen species (Fig. 12–2). For example, manganese ion exposure is implicated in the free radical damage of the basal ganglia causing parkinsonism.

FIGURE 12–2. The Fenton and Haber-Weiss reactions, which are the two most important mechanisms to generate hydroxyl radicals, are both mediated by transition metals. Typical transition metals include iron (Fe^{2+} , shown) or copper (Cu^+).

Heavy Metals. Heavy metal is often loosely used to describe all metals of toxicologic significance, but in reality the term should be reserved to describe only those metals in the lower period of the periodic table, particularly those with atomic masses greater than 200 Da. The chemical properties and toxicologic predilection of this group vary among the elements, but their unifying toxicologic mechanism is electrophilic interference with nucleophilic sulfhydryl-containing enzymes. Some of the heavy metals also participate in the generation of free radicals through Fenton chemistry (Fig. 12–2). The likely determinant of the specific toxicologic effects produced by each metal is the tropism for various physiologic systems, enzymes, or microenvironments; thus lipophilicity, water solubility, ionic size, and other physicochemical parameters are undoubtedly critical. Also, because the chemistry of metals varies dramatically based on the chemical form (ie, organic, inorganic, or elemental), as well as the charge on the metal ion, prediction of the clinical effects of a particular metal is often difficult.

Mercury. Elemental mercury (Hg^0) is unique in that it is the only metal that exists in liquid form at room temperature and as such is capable of creating solid solutions, or amalgams, with other metals. Although it is relatively innocuous if ingested as a liquid, it is readily volatilized (ie, high vapor pressure), transforming it into a significant pulmonary mucosal irritant upon inhalation. In addition, this change in the route of exposure increases its systemic bioavailability. Absorbed, or incorporated, Hg^0 undergoes biotransformation in the erythrocyte and brain to the mercuric (Hg^{2+}) form, which has a high affinity for sulfhydryl-containing molecules, including proteins. This causes a depletion of glutathione in organs such as the kidney and also initiates lipid peroxidation. The mercurous form (Hg^+) is considerably less toxic than the mercuric (Hg^{2+}) form, perhaps because of its reduced water solubility, which limits absorption. Organic mercurial compounds, such as methylmercury and dimethylmercury, are environmentally formed by anaerobic bacteria containing the methylating compound methylcobalamin, a vitamin B_{12} analog (Chap. 98).

Thallium. Another toxicologically important member of the heavy metal group is thallium. Metallic thallium (Tl^0) is used in the production of electronic equipment and is itself minimally toxic. Thallium ions, however, have physicochemical properties that closely mimic potassium ions, allowing them to participate in, and potentially alter, the myriad physiologic activities related to potassium. This property is exploited during a thallium-stress test to assess for myocardial ischemia or infarction. Because ischemic myocardial cells lack adequate energy for normal Na^+/K^+ -ATPase function, they cannot exchange sodium for potassium (or in this scenario radioactive thallium), producing a “cold spot” in the ischemic areas on cardiac scintigraphy (Chap. 102).

Lead. Although lead is not very abundant in the Earth’s crust (only 0.002%), exposure may occur during the smelting

process or from one of its diverse commercial applications. Most of the useful lead compounds are inorganic plumbous (Pb^{2+}) salts, but plumbic (Pb^{4+}) compounds are also used. The Pb^{2+} compounds are typically ionizable, releasing Pb^{2+} when dissolved in a solvent, such as water. Pb^{2+} ions are absorbed in place of Ca^{2+} ions by the gastrointestinal tract and replace Ca^{2+} in certain physiologic processes. This mechanism is implicated in the neurotoxic effect of lead ions. Pb^{4+} compounds tend to be covalent compounds that do not ionize in water. Some of the Pb^{4+} compounds are oxidants. Although elemental lead is not itself toxic, it rapidly develops a coating of toxic lead oxide or lead carbonate on exposure to air or water (Chap. 96).

Metalloids. Although the metalloids (B, Si, Ge, As, Sb, Te, At) share many physical properties with the metals, they are differentiated by their propensity to form compounds with both metals and the nonmetals carbon, nitrogen, or oxygen. Thus, metalloids may be either oxidized or reduced in chemical reactions.

Arsenic. Toxicologically important inorganic arsenic compounds exist in either the pentavalent arsenite (As^{5+}) form or the trivalent arsenate (As^{3+}) form. The reduced water solubility of the arsenate compounds, such as arsenic pentoxide, accounts for its limited clinical toxicity when compared to trivalent arsenic trioxide. The trivalent form of arsenic is primarily a nucleophilic toxin, binding sulfhydryl groups and interfering with enzymatic function (Chaps. 13 and 89).

Nonmetals. The nonmetals (C, N, P, O, S, Se, halogens) are highly electronegative and, unlike the metals, may be toxic in either their compounded or their elemental form. The nonmetals with large electronegativity, such as O_2 or Cl_2 , generally oxidize other elements in chemical reactions. Those with lesser electronegativity, such as C, behave as reducing agents.

Halogens. In their highly reactive elemental form, which is a covalent dimer of halogen atoms, the halogens (F, Cl, Br, I, At) carry the suffix -ine (eg, Cl_2 , chlorine). Halogens require the addition of one electron to complete their valence shell; thus, halogens are strong oxidizing agents. Because they are highly electronegative, they form halides (eg, Cl^- , chloride) by abstracting electrons from less electronegative elements. Thus, the halogen ions, in their stable ionic form, generally carry a charge of -1 . The halides, although much less reactive than their respective elemental forms, are reducing agents. The hydrogen halides (eg, HCl, hydrogen chloride) are gases under standard conditions, but they ionize when dissolved in aqueous solution to form the hydrohalidic acids (eg, HCl, hydrochloric acid). All hydrogen halides except HF (hydrogen fluoride) ionize nearly completely in water to release H^+ and are considered strong acids. Because of its small ionic radius, lack of charge dispersion, and the intense electronegativity of the fluorine atom, HF ionizes poorly and is a weak acid. This specific property of HF has important toxicologic implications (Chap. 107).

Group 0: Inert Gases. Inert gases (He, Ne, Ar, Kr, Xe, Rn), also known as noble gases, maintain completed valence shells and are thus entirely unreactive except under extreme experimental conditions. However, despite their lack of chemical reactivity, the inert gases are toxicologically important as simple asphyxiants. That is, because they displace ambient oxygen from a confined space, hypoxia may occur (Chap. 124). During high-concentration exposure, inert gases may produce anesthesia, and xenon is used as an anesthetic agent. Radon, although a chemically unreactive gas, is radioactive, and prolonged exposure is associated with the development of lung cancer.

Bonds

Electrons are not generally shared evenly between atoms when they form a compound. Instead, unless the bond is between the same elements, as in Cl_2 , one of the elements exerts a larger attraction for the shared electrons. The degree to which an element draws the shared electron is determined by the electronegativity of the element (Fig. 12–3). The electronegativity of each element was catalogued by Linus Pauling and relates to the ionic radius, or the distance between the orbiting electron and the nucleus, and the shielding effects of the inner electrons. The electronegativity rises toward the right of the periodic table, corresponding with the expected charge obtained on an element when it forms a bond. Fluoride ion has the highest electronegativity of all elements, which explains many of its consequential toxicologic properties.

FIGURE 12–3. Electronegativity of the common elements. Note that the inert gases are not reactive and thus do not have

electronegativity.

Several types of bonds exist between elements when they form compounds. When one element gains valence electrons and another loses them, the resulting elements are charged and attract one another in an ionic, or electrovalent, bond. An example is sodium chloride (NaCl), or table salt, in which the electronegativity difference between the elements is 1.9, or greater than the electronegativity of the sodium (Fig. 12–3). Thus, the chloride wrests control of the electrons in this bond. In solid form, ionic compounds exist in a crystalline lattice, but when put into solution, as in the serum, the elements may separate and form charged particles, or ions (Na^+ and Cl^-). The ions are stable in solution, however, because their valence shells contain eight electrons and are complete. The properties of ions differ from both the original atom from which the ion is derived and the noble gas with which it shares electronic structure.

It is important to recognize that when a mole of a salt, such as NaCl (molecular weight 58.45 g/mol), is put in aqueous solution, two moles of particles result. This is because NaCl essentially ionizes fully in water; that is, it produces one mole of Na^+ (23 g/mol) and one mole of Cl^- (35.5 g/mol). For salts that do not ionize completely, less than the intrinsic number of moles are released and the actual quantity liberated can be predicted based on the defined solubility of the compound, or the solubility product constant (K_{sp}). For ions that carry more than a single charge, the term equivalent is often used to denote the number of moles of other particles to which one mole of the substance will bind. Thus, an equivalent of calcium ion will typically bind two moles (or equivalents) of chloride ions (which are monovalent) because calcium ions are divalent. Alternatively stated, a 10% calcium chloride (CaCl_2) aqueous solution contains approximately 1.4 mEq/mL or 0.7 mmol/mL of Ca^{2+} .

Compounds formed by two elements of similar electronegativity have little ionic character because there is little impetus for separation of charge. Instead, these elements share pairs of valence electrons, a process known as covalence. The resultant molecule contains a covalent bond, which is typically very strong and generally requires a high-energy chemical reaction to disrupt it. There is wide variation in the extent to which the electrons are shared between the participants of a covalent bond, and the physicochemical and toxicologic properties of any particular molecule are in part determined by its nature. Rarely is sharing truly symmetric, as in oxygen (O_2) or chlorine (Cl_2). If sharing is asymmetric and the electrons thus exist to a greater degree around one of the component atoms, the bond is polar. However, the presence of a polar bond does not mean that the compound itself is polar. For example, methane contains a carbon atom that shares its valence electrons with four hydrogen atoms, in which there is a small charge separation between the elements (electronegativity {EN} difference = 0.40). However, because the molecule is configured in a tetrahedral formation, there is no notable polarity to the compound; this compound is nonpolar. The lack of polarity suggests that methane molecules have little affinity for other methane molecules and they are held together only by weak intermolecular bonds. This explains why methane is highly volatile under standard conditions and therefore exists as a gas under standard temperature and pressure.

Because the EN differences between hydrogen (EN = 2.20) and oxygen (EN = 3.44) are greater (EN difference = 1.24), the electrons in the hydrogen-oxygen bonds in water are drawn toward the oxygen atom, giving it a partial negative charge and the hydrogen a partial positive charge. Furthermore, because H_2O is angular, not linear or symmetric, water is a polar molecule. Water molecules are held together by hydrogen bonds, which are stronger than other intermolecular bonds (for example, van der Waals forces; see later). These hydrogen bonds have sufficient energy to open many ionic bonds and solvate the ions. In this process, the polar ends of the water molecule surround the charged particles of the dissolved salt. Thus, because there is little similarity between the nonpolar methane and the polar water molecules, methane is not water soluble. Similarly, salts cannot be solvated by nonpolar compounds, and thus a salt, such as sodium chloride, cannot dissolve in a nonpolar solvent, such as carbon tetrachloride.

Alternatively, the stability and irreversibility of the bond between an organic phosphorus insecticide and the cholinesterase enzyme are a result of covalent phosphorylation of an amino acid at the active site of the enzyme. The resulting bond is essentially irreversible in the absence of another chemical reaction (Fig. 113–3).

Compounds may share multiple pairs of electrons. For example, the two carbon atoms in acetylene ($\text{HC}\equiv\text{CH}$) share three pairs of electrons between them, and each shares one pair with a hydrogen. Carbon and nitrogen share three pairs of electrons in forming cyanide ($\text{C}\equiv\text{N}^-$), making this bond very stable and accounting for the large number of xenobiotics capable of liberating cyanide. Complex ions are covalently bonded groups of elements that behave as a single element. For example, hydroxide (OH^-) and sulfate (SO_4^{2-}) form sodium salts as if they were simply the ion of a single element (such as chloride).

Noncovalent bonds, such as hydrogen or ionic bonds, are important in the interaction between ligands and receptors as well as between ion channels and enzymes. These are low-energy bonds and easily broken. Van der Waals forces, also known as London dispersion forces, are intermolecular forces that arise from induced dipoles as a consequence of nonuniform distribution of the molecular electron cloud. These forces become stronger as the atom (or molecule) becomes larger because of the increased polarizability of the larger, more dispersed electron clouds. This accounts for the fact that under standard temperature and pressure, fluorine and chlorine are gases, whereas bromine is a liquid, and iodine is a

solid.

Reduction-Oxidation

Reduction-oxidation (redox) reactions involve the movement of electrons from one atom or molecule to another, and actually comprise two dependent reactions: reduction and oxidation. Reduction is the gain of electrons by an atom that is thereby reduced. The electrons derive from a reducing agent, which in the process becomes oxidized. Oxidation is the loss of electrons from an atom, which is, accordingly, oxidized. An oxidizing agent accepts electrons and, in the process, is reduced. By definition, these chemical reactions involve a change in the valence of an atom. It is also important to note that acid–base and electrolyte chemical reactions involve electrical charge interactions but no change in valence of any of the involved components. The implications of redox chemistry for toxicology are significant. For example, the oxidation of ferrous (Fe^{2+}) to ferric (Fe^{3+}) iron within the hemoglobin molecule creates the dysfunctional methemoglobin molecule (Chap. 127).

Also, elemental lead and mercury are both intrinsically harmless metals but when oxidized to their cationic forms, both produce devastating clinical effects. Additionally, the metabolism of ethanol to acetaldehyde involves a change in the oxidation state of the molecule. In this case, an enzyme, alcohol dehydrogenase, acting as a catalyst oxidizes (ie, removes electrons from) the C-O bond and delivers the electrons to oxidized nicotinamide adenine dinucleotide (NAD^+), reducing it to NADH. As in this last example, oxidation is occasionally used to signify the gain of oxygen by a substance. That is, when elemental iron (Fe^0) undergoes rusting to iron oxide (Fe_2O_3), it is said to oxidize. The use of this term is consistent because in the process of oxidation, oxygen derives electrons from the atom with which it is reacting and combining.

Reactive Oxygen Species. Free radicals are reactive molecules that contain one or more unpaired electrons and are typically neutral but may be anionic or cationic. However, because certain toxicologically important reactive molecules, such as hydrogen peroxide (H_2O_2) and ozone (O_3), do not contain unpaired electrons, the term reactive species is preferred. The reactivity of these molecules directly relates to their attempts to fill their outermost orbitals by receiving an electron; the result is oxidative stress on the biologic system. Molecular oxygen is actually a diradical with two unpaired electrons in the outer orbitals. However, its reactivity is less than that of the other radicals because the unpaired electrons have parallel spins, so catalysts (ie, enzymes or metals) are typically involved in the use of oxygen in biologic processes.

Reactive species are continuously generated as a consequence of endogenous metabolism, and there is an efficient detoxification system for their control. However, under conditions of either excessive endogenous generation or exposure to exogenous reactive species, the physiologic defenses against these toxic products are overwhelmed. When this occurs, reactive species induce direct cellular damage as well as initiate a cascade of oxidative reactions that perpetuate the toxic damage.

Intracellular organelles, particularly the mitochondria, may also be disrupted by various reactive species. This causes further injury to the cell as energy failure occurs. This initial damage is exacerbated by the activation of the host inflammatory response by chemokines that are released from cells in response to reactive species-induced damage. This inflammatory response aggravates cellular damage. The resultant membrane dysfunction or damage causes cellular apoptosis or necrosis.

The most important reactive oxygen species in medical toxicology are derived from oxygen, although those derived from nitrogen are also important. Table 12–1 lists some of the important reactive oxygen and nitrogen species.

TABLE 12–1. Structure of Important Reactive Species

Structure	
Reactive Oxygen Species	
<i>Free radicals</i>	
Hydroxyl radical	OH•
Alcoxyl radical	RO•
Peroxyl radical	ROO•
Superoxide radical	O ₂ • ⁻
<i>Nonradicals</i>	
Hydrogen peroxide	H ₂ O ₂
Hypochlorous acid	HOCl
Singlet oxygen	[O] or ¹ O ₂
Ozone	O ₃
Reactive Nitrogen Species	
<i>Free radicals</i>	
Nitric oxide	NO•
Nitrogen dioxide	NO ₂ •
<i>Nonradicals</i>	
Peroxynitrite anion	ONOO ⁻
Nitronium cation	NO ₂ ⁺

The biradical nature of oxygen explains both the physiologic and toxicologic importance of oxygen in biologic systems. Physiologically, the majority of oxygen is used by the body to serve as the ultimate electron acceptor in the mitochondrial electron transport chain. In this situation, four electrons are added to each molecule of oxygen to form two water molecules ($O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$).

Superoxide ($O_2^{\cdot-}$) is “mutated” from oxygen within neutrophil and macrophage lysosomes as part of the oxidative burst, which serves to help eliminate infectious agents and damaged cells. Superoxide may subsequently be enzymatically converted, or “dismutated,” into hydrogen peroxide by superoxide dismutase (SOD). Hydrogen peroxide may be subsequently converted into hypochlorous acid by the enzymatic addition of chloride by myeloperoxidase. Both hydrogen peroxide and hypochlorite ion are more potent reactive oxygen species than superoxide. However, this lysosomal protective system may also be responsible for tissue damage following poisoning as the innate inflammatory response attacks xenobiotic-damaged cells. Examples include acetaminophen (APAP)-induced hepatotoxicity ([Chap. 35](#)), carbon monoxide neurotoxicity ([Chap. 125](#)), and chlorine-induced pulmonary toxicity ([Chap. 124](#)), each of which may be altered, at least in experimental systems, by the addition of scavengers of reactive species.

Although superoxide and hydrogen peroxide are reactive species, it is their conversion into the hydroxyl radical (OH•) that accounts for their most consequential effects. The hydroxyl radical is generated by the Fenton reaction ([Fig. 12–2](#)), in which hydrogen peroxide is decomposed in the presence of a transition metal. This catalysis typically involves Fe^{2+} , Cu^+ , Cd^{2+} , Cr^{5+} , Ni^{2+} , or Mn^{2+} . The Haber-Weiss reaction ([Fig. 12–2](#)), in which a transition metal catalyzes the combination of superoxide and hydrogen peroxide, is the other important means of generating the hydroxyl radical. Alternatively, superoxide dismutase, within the erythrocyte, contains an ion of copper (Cu^{2+}) that participates in the catalytic reduction of superoxide to hydrogen peroxide and the subsequent detoxification of hydrogen peroxide by glutathione peroxidase or catalase.

Transition metal cations may bind to the cellular nucleus and locally generate reactive oxygen species, most importantly hydroxyl radicals. This results in DNA strand breaks and modification, accounting for the mutagenic effects of many transition metals. In addition to the important role that transition metal chemistry plays following iron or copper salt poisoning, the long-term consequences of chronic transition metal poisoning are exemplified by asbestos. The iron contained in asbestos is the origin of the Fenton-generated hydroxyl radicals that are responsible for the pulmonary fibrosis and cancers associated with long-term exposure.

The most important toxicologic effects of reactive oxygen species occur on the cell membrane, and are caused by the initiation by hydroxyl radicals of the lipid peroxidative cascade. The alteration of these lipid membranes ultimately causes membrane destruction. Identification of released oxidative products such as malondialdehyde is a common method of assessing lipid peroxidation.

Under normal conditions, there is a delicate balance between the formation and immediate detoxification of reactive oxygen species. For example, the conversion of the superoxide radical to hydrogen peroxide via SOD is rapidly followed

by the transformation of hydrogen peroxide to water by glutathione peroxidase or catalase. Furthermore, the fact that transition metals exist in “free” form in only minute quantities in biologic systems minimizes the formation of hydroxyl radicals; that is, cells have developed extensive systems by which transition metal ions can be sequestered and rendered harmless. Ferritin (binds iron), ceruloplasmin (binds copper), and metallothionein (binds cadmium) are all specialized proteins that safely sequester transition metal ions. Certain proteins and enzymes such as hemoglobin or SOD have critical biological functions associated with the transition metals at their active sites.

Detoxification of certain reactive species is difficult because of their extreme reactivity. Widespread antioxidant systems typically act to trap reactive species before tissue damage occurs. An example is the availability of glutathione, a reducing agent and nucleophile, which prevents both exogenous oxidants from producing hemolysis and the APAP metabolite N-acetyl-p-benzoquinoneimine (NAPQI) from damaging the hepatocyte ([Chap. 35](#)).

The key reactive nitrogen species is nitric oxide. At typical physiologic concentrations, this radical is responsible for vascular endothelial relaxation through stimulation of guanylate cyclase. However, during oxidative burst, high concentrations of nitric oxide are formed from L-arginine. At these concentrations, nitric oxide is directly damaging to tissue and also reacts with the superoxide radical to generate the peroxynitrite anion. This is particularly important because peroxynitrite may spontaneously degrade to form the hydroxyl radical. Peroxynitrite ion is implicated in both the delayed neurologic effects of carbon monoxide poisoning and the hepatic injury from APAP.

Redox cycling. Although transition metals are an important source of reactive species, certain xenobiotics are also capable of independently generating reactive species. Most do so through a process called redox cycling, in which a molecule accepts an electron from a reducing agent and subsequently transfers that electron to oxygen, generating the superoxide radical. At the same time, this second reaction regenerates the parent molecule, which itself can gain another electron and restart the process. The toxicity of paraquat ([Chap. 112](#)) is selectively localized to pulmonary endothelial cells. Its pulmonary toxicity results from redox cycling generation of reactive oxygen species ([Fig. 112–3](#)). A similar process, localized to the heart, occurs with anthracycline antineoplastics such as doxorubicin.

Acid–Base Chemistry

Water is amphoteric, which means that it can function as either an acid or a base, much the same way as the bicarbonate ion (HCO_3^-). In fact, because of the amphoteric nature of water, H^+ , despite the nomenclature, does not ever actually exist in aqueous solution; rather, it is covalently bound to a molecule of water to form the hydronium ion (H_3O^+). However, the term H^+ , or proton, is used for convenience.

Even in a neutral solution, a tiny proportion of water is always undergoing ionization to form both H^+ and OH^- in exactly equal amounts. By convention, however, it is the quantity of H^+ that is measured to determine the acidity or alkalinity of the solution. The units for this measurement are pH, which is $-\log[\text{H}^+]$. In a perfect system at equilibrium, the concentration of H^+ ions in water is precisely 0.0000001, or 10^{-7} , moles/L and that of OH^- is the same. The number of H^+ ions increases when an acid is added to the solution and falls when an alkali is added. The negative log of 10^{-7} is 7, and the pH of a neutral aqueous solution is thus 7. In actuality, the pH of water is approximately 6 because of dissolution of ambient carbon dioxide to form carbonic acid ($\text{H}_2\text{O} + \text{CO}_2 \rightarrow \text{H}_2\text{CO}_3$), which ionizes to form H^+ and bicarbonate (HCO_3^-).

There are many definitions of acid and base. The three commonly used definitions are those advanced by (1) Svante Arrhenius, (2) Brønsted and Lowry, and (3) Lewis. Because the focus is on physiologic systems, which are aqueous, the original definition by the Swedish chemist Arrhenius is the most practical. In this view, an acid releases hydrogen ions, or protons (H^+), in water. Similarly, a base produces hydroxyl ions (OH^-) in water. Thus, hydrogen chloride (HCl), a neutral gas under standard conditions, dissolves in water to liberate H^+ and is therefore an acid.

For nonaqueous solutions, the Brønsted-Lowry definition is preferable. An acid, in this schema, is a substance that donates a proton and a base is one that accepts a proton. Thus, any molecule that has a hydrogen in the 1+ oxidation state is technically an acid, and any molecule with an unbound pair of valence electrons is a base. Because most of the acids or bases of toxicologic interest have ionizable protons or available electrons, respectively, the Brønsted-Lowry definition is most often considered when discussing acid–base chemistry (ie, $\text{HA} + \text{H}_2\text{O} \rightarrow \text{H}_3\text{O}^+ + \text{A}^-$; $\text{B}^- + \text{H}_2\text{O} \rightarrow \text{HB} + \text{OH}^-$). However, this is not a defining property of all acids or bases.

The Lewis classification offers the least-restrictive definition of such substances. A Lewis acid is an electron acceptor and a Lewis base is an electron donor.

Simplistically, acids are sour and turn litmus paper red; bases feel slippery (due to the dissolution of skin), are bitter, and turn litmus paper blue. Of course, the tasting and tactile assessment of substances to determine their acid-base status is not recommended.

Because acidity and alkalinity are determined by the number of available H^+ ions, it is useful to classify chemicals by their effect on the H^+ concentration. Strong acids ionize almost completely in aqueous solution and very little of the parent compound remains. Thus, 0.001 (or 10^{-3}) mole of HCl, a strong acid, added to 1 L of water produces a solution with a pH

of 3. Weak acids, on the other hand, reach an equilibrium between parent and ionized forms, and thus do not alter the pH to the same degree as a similar quantity of a strong acid. This chemical notation defines the strength or weakness of an acid and should not be confused with the concentration of the acid. Thus, the pH of a dilute strong acid solution may be substantially less than that of a concentrated weak acid (Table 12–2).

TABLE 12–2. pH of 0.10 M Solutions of Common Acids and Bases Represents the Strength of the Acid or Base

<i>Acid/Base</i>	<i>pH</i>
HCl (hydrochloric acid)	1.1
H ₂ SO ₄ (sulfuric acid)	1.2
H ₂ SO ₃ (sulfurous acid)	1.5
H ₃ PO ₄ (phosphoric acid)	1.5
HF (hydrofluoric acid)	2.1
CH ₃ CO ₂ H (acetic acid)	2.9
H ₂ CO ₃ (carbonic acid)	3.8
H ₂ S (hydrogen sulfide)	4.1
NH ₄ Cl (ammonium chloride)	4.6
HCN (hydrocyanic acid)	5.1
NaHCO ₃ (sodium bicarbonate)	8.3
NaCH ₃ CO ₂ (sodium acetate)	8.9
Na ₂ HPO ₄ (sodium hydrogen phosphate)	9.3
Na ₂ SO ₃ (sodium sulfite)	9.8
NaCN (sodium cyanide)	11.0
NH ₄ OH (ammonium hydroxide)	11.1
Na ₂ CO ₃ (sodium carbonate)	11.6
Na ₃ PO ₄ (sodium phosphate)	12.0
NaOH (sodium hydroxide)	13.0

The degree of ionization of an acid is determined by the pK_a , or the negative log of the ionization constant, which represents the pH at which an acid is half dissociated in solution. The same relationship applies to the pK_b of an alkali, although pK_b is rarely used and the degree of ionization of bases is also expressed as pK_a (of note, $pK_a = 14 - pK_b$). The lower the pK_a , the stronger the acid; the higher the pK_a , the stronger the base. The pK of a strong acid is clinically irrelevant because it is nearly fully ionized under all but the most extremely acidic conditions. Importantly, knowledge of the pK_a does not itself denote the strength of an acid or an alkali. To some extent, this quality may be predicted by its chemical structure or reactivity, or it may be obtained through direct measurement or from a reference source.

Because only uncharged compounds cross lipid membranes spontaneously, the pK_a has strong clinical relevance. Salicylic acid, a weak acid with a pK_a of 3, is nonionized in the stomach (pH = 2) and passive absorption occurs (Fig. 9–3). Because it is predominantly in the ionized form (ie, salicylate) in blood, which has a pH of 7.4, little of the ionized blood-borne salicylate passively enters the tissues. However, because in overdose the serum salicylate rises considerably, enough enters the tissue to result in clinical toxicity. Salicylate is the conjugate base of a weak acid (and thus itself a strong base). It diffuses into the mitochondrial intermembrane space (between the inner and outer mitochondrial membrane), where abundant protons exist that have been transported there via the electron transport chain of this organelle (Fig. 13–3). Because salicylate is a strong base, it protonates easily in this environment. In this nonionized form, some of the salicylic acid may pass through the inner mitochondrial membrane, into the mitochondrial matrix, and again establish equilibrium by losing a proton. This is the uncoupling of oxidative phosphorylation, dispersing highly concentrated protons in the intermembrane space that are normally used to generate adenosine triphosphate (Chap. 13). Uncoupling produces a

metabolic acidosis, and this shifts the blood equilibrium of salicylate toward the nonionized, protonated form, enabling salicylic acid to cross the blood–brain barrier. Presumably, once in the brain, the salicylate uncouples the metabolic activity of neurons with the subsequent development of cerebral edema. This is the rationale for serum alkalization in patients with aspirin overdose (Chap. 39).

In a similar manner, alkalization of the patient’s urine prevents reabsorption by ionization of the urinary salicylate. Salicylate anion excreted into acidic urine may protonate, and the uncharged moiety may then back-diffuse across the renal tubular epithelium and re-enter the body. Alkalization of the urine “traps” salicylate in the deprotonated form, enhancing excretion. Conversely, because cyclic antidepressants are organic bases, alkalization of the urine reduces their ionization and actually decreases the urinary elimination of the drug. However, in the management of cyclic antidepressant poisoning, because the other beneficial effects of sodium bicarbonate on the sodium channel outweigh the negative effect on drug elimination, serum alkalization is recommended (Chap. 71).

ORGANIC CHEMISTRY

The study of carbon-based chemistry and the interaction of inorganic molecules with carbon-containing compounds is called organic chemistry, because the chemistry of living organisms is carbon based. Biochemistry (Chap. 13) is a subdivision of organic chemistry; it is the study of organic chemistry within biologic systems. This section reviews many of the salient points of organic chemistry, focusing on those with the most applicability to medicine and the study of toxicology: nomenclature, bonding, nucleophiles and electrophiles, stereochemistry, and functional groups.

Chemical Properties of Carbon

Carbon, atomic number 6, has a molecular weight of 12.011 g/mol. With few exceptions (notably cyanide ion and carbon monoxide), carbon forms four bonds in stable organic molecules. In organic compounds, carbon is commonly bonded to other carbon atoms, as well as to hydrogen, oxygen, nitrogen, or halides. Under certain circumstances, carbon can be bonded to metals, as is the case with methylmercury.

Nomenclature

The most systematic method to name organic compounds is in accordance with standards adopted by the International Union of Pure and Applied Chemistry (IUPAC); these names are infrequently used, especially for larger molecules, and alternative names are common. The complete details of the IUPAC naming system are beyond the scope of this text and can be reviewed elsewhere (www.iupac.org), but a brief description of the fundamentals of this system is included here.

The carbon backbone of a molecule serves as the basis of its chemical name. Once the carbon backbone has been identified and named, substituents (atoms or groups of atoms that substitute for hydrogen atoms) are identified, named, and numbered. The number refers to the carbon to which the substituent is attached. Some of the common substituents in organic chemistry are –OH (hydroxy), –NH₂ (amino), –Br (bromo), –Cl (chloro), and –F (fluoro). Substituents are then alphabetized and placed as prefixes to the carbon chain.

As an example, consider the molecule 2-bromo-2-chloro-1,1,1-trifluoroethane. The molecule has a two-carbon backbone (ethane), three fluoride atoms on the first carbon, a bromine atom on the second carbon, and a chlorine atom on the second carbon (Fig. 12–4A). A basic understanding of a few simple rules of nomenclature thus allows one to quickly generate the molecular structure of a familiar compound, halothane.

FIGURE 12–4. Nomenclature. (A) 2-Bromo-2-chloro-1,1,1-trifluoroethane, or halothane. (B) [1R-(exo,exo)]-3-(Benzoyloxy)-8-methyl-8-azabicyclo[3,2,1]-octane-2-carboxylic acid methyl ester, or cocaine.

Although the above mentioned rules suffice to name simple structures, they are inadequate to describe many others, such as molecules with complex branching or ring structures. The IUPAC rules for naming compounds such as [1R-(exo,exo)]-3-(benzoyloxy)-8-methyl-8-azabicyclo[3,2,1]octane-2-carboxylic acid methyl ester, for example, are too complex to include

here. Fortunately, many compounds with complex chemical names have simpler names for day-to-day use; as an example, this molecule is commonly referred to as cocaine (Fig. 12-4B).

Cocaine is an example of a common or trivial name; one without a systematic basis, but which is generally accepted as an alternative to frequently unwieldy proper chemical names. Common names may refer to the origin of the substance; for example, cocaine is derived from the coca leaf, and wood alcohol (methanol) can be prepared from wood. Alternatively, a common name may refer to the way in which a compound is used; rubbing alcohol is a common name for isopropanol. Common names are often imprecise and may generate some confusion, however, as evidenced by the fact that rubbing alcohol, when commercially marketed, may be either ethanol or isopropanol.

An even less precise system of nomenclature is the use of street names. A street name is a slang term for a drug of abuse, such as “blow” (cocaine), “weed” (marijuana), or “smack” (heroin). The street name ecstasy refers to the stimulant 3,4-methylenedioxymethamphetamine (MDMA), which is most frequently consumed in pill form. It would stand to reason that liquid ecstasy might refer to a solution of MDMA, but street names are not necessarily logical. Instead, liquid ecstasy refers to the drug γ -hydroxybutyrate, a sedative-hypnotic with a completely different pharmacologic and toxicologic profile. Furthermore, there are no standards for the content of ecstasy, and many street pills contain other chemicals.

A final consideration must be given to product names. Product names are trade names under which a given compound might be marketed, and are frequently different from both the chemical name and common name. Thus, the inhalational anesthetic in Fig. 12-4A with the chemical name 2-bromo-2-chloro-1,1,1-trifluoroethane has the common name halothane and the trade name Fluothane.

Bonding in Organic Chemistry

While much of the bonding in inorganic chemistry is ionic, the vast majority of bonding in organic molecules is covalent. Whereas electrons in ionic bonds are described as predominately “belonging” to one atom or another, electrons in covalent bonds are shared between two atoms; this type of bonding occurs when the difference in electronegativity between two atoms is insufficient for one atom to wrest control of an electron from another. Bonds are represented by lines between the atoms: one for a single bond, two for a double bond, and three for a triple bond.

Nucleophiles and Electrophiles

Many organic reactions of toxicologic importance can be described as the reactions of nucleophiles with electrophiles. Nucleophiles (literally, nucleus-loving) are species with increased electron density, frequently in the form of a lone pair of electrons (as in the cases of cyanide ion and carbon monoxide). Nucleophiles, by virtue of their increased electron density, have an affinity for atoms or molecules that are electron deficient; such moieties are called electrophiles (literally, electron-loving). The electron deficiency of electrophiles can be described as absolute or relative. Absolute electron deficiency occurs when an electrophile is charged, as is the case with cations such as Pb^{2+} and Hg^{2+} . Relative electron deficiency occurs when one atom or group of atoms shifts electrons away from a second atom, making the second atom relatively electron deficient. This is the case for the neurotoxin 2,5-hexanedione (Fig. 12-5); the electronegative oxygen of the carbon-oxygen double bond pulls electron density away from the second and fifth carbon atoms of this molecule, making these carbon atoms electrophilic.

FIGURE 12-5. Chemical properties of 2,5-hexanedione. Arrows designate the electrophilic carbon atoms.

The reaction of a nucleophile with an electrophile involves the movement of electrons, by forming or breaking bonds. This movement of electrons is frequently denoted by the use of curved arrows, which better demonstrates how the nucleophile and electrophile interact. The interaction of acetylcholinesterase with acetylcholine, organic phosphorus pesticides, and pralidoxime hydrochloride provides an excellent example of the way in which nucleophiles and electrophiles interact, and of how the use of curved arrow notation can lead to better understanding of the reactions involved.

Under normal circumstances, the action of acetylcholine is terminated when the serine residue in the active site of acetylcholinesterase attacks this neurotransmitter, forming a transient serine-acetyl complex and liberating choline. This serine-acetyl complex is then rapidly hydrolyzed, producing an acetic acid molecule and regenerating the serine residue for another round of the reaction (Fig. 12-6A). In the presence of an organic phosphorus pesticide, however, this serine residue attacks the electrophilic phosphate atom, forming a stable serine-phosphate bond, which is not hydrolyzed (Fig. 12-6B). The enzyme, thus inactivated, can no longer break down acetylcholine, leading to an increase of this

neurotransmitter in the synapse and possibly a cholinergic crisis.

FIGURE 12-6. The reactions of acetylcholinesterase (AChE), organic phosphorus compounds, and pralidoxime hydrochloride (2-PAM). Curved arrows represent the movement of electrons as bonds are formed or broken. (A) Normal hydrolysis of acetylcholine by AChE. (B) Inactivation (phosphorylation) of AChE by organic phosphorus compound. (C) Reactivation by 2-PAM of functional AChE.

The enzyme can be reactivated, however, by the use of another nucleophile. Pralidoxime hydrochloride (2-PAM) is referred to as a site-directed nucleophile. Because part of its chemical structure (the charged nitrogen atom) is similar to the choline portion of acetylcholine, this antidote is directed to the active site of acetylcholinesterase. Once in position, the nucleophilic oxime moiety (-NOH) that is remote from the positive charge of 2-PAM attacks the electrophilic phosphate moiety. This displaces the serine residue, regenerating the enzyme (Fig. 12-6C). A further discussion of organic phosphorus compound toxicity and the use of 2-PAM can be found in Chap. 113 and Antidotes in Depth: A33, respectively.

A second toxicologically important electrophile is NAPQI (Fig. 12-7). NAPQI is formed when the endogenous detoxification pathways of APAP metabolism (glucuronidation and sulfation) are overwhelmed (Chap. 35). As a result of the electron configuration of NAPQI, the carbon atoms adjacent to the carbonyl carbon (a carbon that is double bonded to an oxygen) are very electrophilic; the sulfur groups of cysteine residues of hepatocyte proteins react with NAPQI to form a

characteristic adduct (formed when one compound is added to another), 3-(cystein-S-yl) APAP, in a multistep process. These adducts are released as hepatocytes die, and can be found in the blood of patients with APAP-related liver toxicity. **Figure 12–7** diagrams the mechanism of the protein–NAPQI reaction (**Chap. 35**).

FIGURE 12–7. The reaction of cysteine residues on hepatocyte proteins with N-acetyl-p-benzoquinoneimine (NAPQI) to form the characteristic adducts 3-(cystein-S-yl) APAP.

Nucleophiles can be described by their strength, which by convention is related to the rate at which they react with the reference electrophile CH_3I . Of more use in pharmacology and toxicology, however, are the descriptive terms “hard” and “soft.” Although imprecise, the designations hard and soft help to predict, qualitatively, how nucleophiles and electrophiles interact with one another.

Hard species have a charge (or partial charge) that is highly localized; that is, their charge-to-radius ratio is high. Hard nucleophiles are molecules in which the electron density or lone pair is tightly held; fluoride, a small atom that cannot spread its electron density over a large area, is an example. Similarly, hard electrophiles are species in which the positive charge cannot be spread over a large area; ionized calcium, a small ion, is a hard electrophile.

Soft species, on the other hand, are capable of delocalizing their charge over a larger area. In this case the charge-to-mass ratio is low, either because the atom is large or because the charge can be spread over a number of atoms within a given molecule. Sulfur is the prototypical example of a soft nucleophile and the lead ion, Pb^{2+} , is a typical soft electrophile.

The utility of this classification lies in the observation that hard nucleophiles tend to react with hard electrophiles, and soft nucleophiles with soft electrophiles. For example, a principal toxicity of fluoride ion poisoning (**Chap. 107**) is hypocalcemia; this is because the fluoride ions (hard nucleophiles) readily react with calcium ions (hard electrophiles). On the other hand, the soft nucleophile lead is effectively chelated by soft electrophiles such as the sulfur atoms in the chelators dimercaprol (**Antidotes in Depth: A25**) and succimer (**Antidotes in Depth: A26**).

Isomerism

Isomerism describes the different ways in which molecules with the same chemical formula (ie, the same number and types of atoms) can be arranged to form different compounds. These different compounds are called isomers. Isomers always have the same chemical formula but differ either in the way that atoms are bonded to each other (constitutional isomers) or in the spatial arrangement of these atoms (geometric isomers or stereoisomers).

Constitutional isomers are conceptually the easiest to understand, because a quick glance shows them to be very different molecules. The chemical formula $\text{C}_2\text{H}_6\text{O}$, for example, can refer to either dimethyl ether or ethanol (**Fig. 12–8**). These molecules have very different physical and chemical characteristics, and they have little in common other than the number and type of their atomic constituents.

FIGURE 12–8. Two molecules with chemical formula $\text{C}_2\text{H}_6\text{O}$. (A) Dimethylether. (B) Ethanol (ethyl alcohol).

Stereoisomerism, also referred to as geometric isomerism, refers to the different ways in which atoms of a given molecule, with the same number and types of bonds, might be arranged. The most important type of stereoisomerism in pharmacology and toxicology is the stereochemistry around a stereogenic (sometimes called chiral) carbon.

Consider the two representations of halothane shown in **Fig. 12–9**. In this figure the straight solid lines and the atoms to which they are bonded exist in the plane of the paper, the solid triangle and the atom to which it is bonded are coming out of

the paper, and the dashed triangle and the atom to which it is bonded are receding into the paper. It is clear that, for the molecules in **Figs. 12–9A and B**, no amount of rotation or manipulation will make these molecules superimposable. They are, therefore, different compounds.

FIGURE 12–9. The graphic representation of the enantiomers of haloethane.

These molecules are enantiomers or optical isomers. They differ only in the way in which their atoms are bonded to a chiral carbon. It is important to define the stereochemical configuration of these two molecules, which can be done in one of two ways. In the first classification—the d(+)/l(–) system—molecules are named empirically based on the direction in which they rotate plane-polarized light. Each enantiomer will rotate plane-polarized light in one direction; the enantiomer that rotates light clockwise (to the right) is referred to as d(+), or dextrorotatory; the l(–), or levorotatory enantiomer rotates plane-polarized light in a counterclockwise fashion (to the left).

Alternatively, enantiomers can be named using an elaborate and formal set of rules known as Cahn-Ingold-Prelog. These rules establish priority for substituents, based primarily on molecular weight, and then use the arrangement of substituents to assign a configuration. To correctly assign configuration in this system, the molecule is rotated into a projection in which the chiral carbon is in the plane of the page, the lowest priority substituent is directly behind the chiral carbon (and therefore behind the plane of the page), and the other three substituents are arranged around the chiral carbon. **Figure 12–10** assigns Cahn-Ingold-Prelog priority to the haloethane enantiomers of **Fig. 12–9**, and rearranges the molecules in the appropriate projections.

FIGURE 12–10. R and S enantiomers of haloethane. **(A)** The substituents increase in a clockwise fashion, so the configuration is R. **(B)** The substituents increase in a counterclockwise fashion, so the configuration is S. In this projection, hydrogen atoms are directly behind the carbon atoms.

If the priority of the substituents increases as one moves clockwise (to the right), the enantiomer is R (Latin, rectus = right); if it increases as one moves counterclockwise, the enantiomer is S (Latin, sinister = left). Thus, **Fig. 12–10A** is the R enantiomer of haloethane and **Fig. 12–10B** is the S enantiomer.

Enantiomers have identical physical properties, such as boiling point, melting point, and solubility in different solvents; they differ from each other in only two significant ways. The first, as mentioned before, is that enantiomers rotate plane-polarized light in opposite directions; this point has no practical toxicologic importance. The second is that enantiomers may interact in very different ways with other chiral structures (such as proteins and other cell receptors), which is of both pharmacologic and toxicologic significance.

The best analogy to explain the toxicologic and pharmacologic importance of stereochemistry is that of the way a hand

(analogous to a molecule of xenobiotic) fits into a glove (analogous to the biologic site of activity). Consider the left hand as the S enantiomer and the right hand as the R enantiomer. There are, qualitatively, three different ways in which the hand can fit into (interact with) a glove.

First, if the glove is pliable and relatively fluid (such as a disposable latex glove), it can accept either the left hand or the right hand without difficulty; this is the case for halothane, whose R and S enantiomers interact with cell membranes rather than specific receptors and possess equal activity. Second, if a glove is constructed with greater (but imperfect) specificity, one hand will fit well and the other poorly; this is the case for many substances, such as epinephrine and norepinephrine, whose naturally occurring levorotatory enantiomers are 10-fold more potent than the synthetic dextrorotatory enantiomers. Finally, a glove can be made with exquisite precision, such that one hand fits perfectly, while the other hand does not fit at all. This is the case for physostigmine, in which the (-) enantiomer is biologically active, whereas the (+) enantiomer is inactive.

Even the above analogy is oversimplified, however, because one enantiomer of a drug can be an agonist, while the other enantiomer is an antagonist. Dobutamine, for example, has one stereogenic carbon and thus two stereoisomers. At the α_1 receptor, l-dobutamine is a potent agonist and d-dobutamine is a potent antagonist. Because dobutamine is marketed as a racemic mixture (a racemic mixture is a 1:1 mixture of enantiomers), however, these effects cancel each other out. Interestingly, at the β_1 receptor, d- and l-dobutamine have unequal agonist effects, with d-dobutamine approximately 10 times more potent than l-dobutamine.

Functional Groups

There is perhaps no concept in organic chemistry as powerful as that of the functional group. Functional groups are atoms or groups of atoms that confer similar reactivity on a molecule; of less importance is the molecule to which it is attached. Alcohols, carboxylic acids, and thiols are functional groups; hydrocarbons are generally not considered functional groups per se, but rather are the structural backbone to which functional groups are attached. The functional groups discussed below are included to illustrate important principles, not because they represent an exhaustive list of important functional groups in toxicology.

Hydrocarbons, as their name implies, consist of only carbon and hydrogen. Alkanes are hydrocarbons that contain no multiple bonds; they may be straight chain, usually designated by the prefix n- butane [by the prefix n- as in n-butane (Fig. 12-11A) or iso- if branched, as in isobutane] (Fig. 12-11B). Alkenes contain carbon-carbon double bonds. Alkynes, which contain carbon-carbon triple bonds, are of limited toxicologic importance. Butane (lighter fluid) is an alkane, and gasoline is a mixture of alkanes.

FIGURE 12-11. Two isomers of the four-carbon alkane, butane. (A) n-Butane. (B) Isobutane.

Hydrocarbons are of toxicologic importance for two reasons: they are widely abused as inhalational drugs for their central nervous system (CNS) depressant effects, and they can cause profound toxicity when aspirated. Although these effects are physiologically disparate, they are readily understood in the context of the chemical characteristics of the hydrocarbon functional group.

Hydrocarbons do not contain polar groups (ie, or groups that introduce full or partial charges into the molecule). As such, they interact readily with other nonpolar substances, such as lipids or lipophilic substances. Hydrocarbons readily interact with the myelin of the CNS, disrupting normal ion channel function and causing CNS depression. When aspirated, hydrocarbons interact with the fatty acid tail of surfactant, dissolving this protective substance and contributing to acute respiratory distress syndrome (Chap. 108).

Alcohols possess the hydroxyl (-OH) functional group, which adds polarity to the molecule and makes alcohols highly soluble in other polar substances, such as water. For example, ethane gas (CH₃CH₃) has negligible solubility in water, whereas ethanol (CH₃CH₂OH) is miscible, or infinitely soluble, in water. In biologic systems, alcohols are generally CNS depressants, but they can also act as nucleophiles. Ethanol may react with cocaine to form cocaethylene, a longer-acting and more vasoactive substance than cocaine itself (Fig. 12-12; Chap. 78).

FIGURE 12–12. Transesterification reaction of cocaine with ethanol (A) to form cocaethylene and methanol (B).

Alcohols can be primary, secondary, or tertiary, in which the reference carbon is bonded to one, two, or three carbons in addition to the hydroxyl group. Methanol, in which the reference carbon is bonded to no other carbons, is not a primary alcohol per se but shares many of the reactivity patterns of primary alcohols. The difference between primary, secondary, and tertiary structures is important, because although the alcohol functional group imparts many qualities to the molecule, the degree of substitution can affect the chemical reactivity. Primary alcohols can undergo multistep oxidation to form carboxylic acids, whereas secondary alcohols generally undergo one-step metabolism to form ketones, and tertiary alcohols do not readily undergo oxidation. This is a point of significant toxicologic importance, and is discussed in more detail later.

Alcohols can be named in many ways; the most common is to add *-ol* or *-yl alcohol* to the appropriate prefix. If the alcohol group is bonded to an interior carbon, the number to which the carbon is bonded precedes the suffix.

Carboxylic acids contain the functional group *-COOH*. As their name implies, they are (weakly) acidic, and the pK_a of carboxylic acids is generally 4 or 5, depending on the substitution of the molecule. Small-molecular-weight carboxylic acids are capable of producing an elevated anion gap metabolic acidosis, which is true whether the acids are endogenous or exogenous. Examples of endogenous acids are β -hydroxybutyric acid and lactic acid; examples of exogenous acids are formic acid (produced by the metabolism of methanol) and glycolic, glyoxylic, and oxalic acids (produced by the metabolism of ethylene glycol). Carboxylic acids are named by adding *-oic acid* to the appropriate prefix; the four-carbon straight-chain carboxylic acid is thus butanoic acid.

Thiols contain a sulfur atom, which usually functions as a nucleophile. The sulfur atom of N-acetylcysteine can regenerate glutathione reductase and can also react directly with NAPQI to detoxify this electrophile. The sulfur atoms of many chelators, such as dimercaprol and succimer, are nucleophiles that are very effective at chelating electrophiles such as heavy metals. Thiols are generally named by adding the word *thiol* to the appropriate base. Thus, a two-carbon thiol is ethane thiol.

As noted above, molecules with a given functional group often have more in common with molecules with the same functional group than they have in common with the molecules from which they were derived. The alkanes methane, ethane, and propane are straight-chain hydrocarbons with similar properties. All are gases at room temperature, have almost no solubility in water, and have similar melting and boiling points. When these molecules are substituted with one or more hydroxide functional groups, they become alcohols: examples are methanol, ethanol, ethylene glycol (a glycol is a molecule that contains two alcohol functional groups), the primary alcohol 1-propanol, and the secondary alcohol 2-propanol (isopropanol). Each of these alcohols is a liquid at room temperature, and all are very water soluble. All have boiling points that are markedly different from the alkane from which they were derived, and quite close to each other.

In addition to conferring different physical properties on the molecule, the addition of the alcohol functional group also confers different chemical properties and reactivities. For example, methane, ethane, and propane are virtually incapable of undergoing oxidation in biologic systems. The alcohols formed by the addition of one or more hydroxyl groups, however, are readily oxidized by alcohol dehydrogenase (Fig. 12–13).

FIGURE 12–13. Oxidative metabolism of (A) methanol, (B) ethanol, and (C) isopropanol. Note that acetone does not undergo further oxidation in vivo. ADH = alcohol dehydrogenase; ALDH = aldehyde dehydrogenase.

As Fig. 12–13 indicates, the oxidation of the primary alcohols methanol and ethanol results in the formation of aldehydes (functional groups in which a carbon atom contains a double bond to oxygen and a single bond to hydrogen), whereas the oxidation of the secondary alcohol isopropanol results in the formation of a ketone (a functional group in which a carbon is double-bonded to an oxygen atom and single-bonded to two separate carbon atoms). Although both aldehydes and ketones contain the carbonyl group (a carbon-oxygen double bond), aldehydes and ketones are distinctly different functional groups, and they have different reactivity patterns. For instance, aldehydes can undergo enzymatic oxidation to carboxylic acids (Figs. 12–13A and B), whereas ketones cannot (Fig. 12–13C).

It is here that recognition of functional groups helps to understand the potential toxicity of an alcohol. Methanol, ethanol, and isopropanol are all alcohols; as such, their toxicity before metabolism is expected to be (and in fact is) quite similar to that of ethanol, producing CNS sedation. Because these toxins are primary and secondary alcohols, all can be metabolized to a carbonyl compound, either an aldehyde or a ketone. Here, however, the functional groups on the molecules have changed; whereas aldehydes can be metabolized to carboxylic acids (which can, in turn, cause an anion gap acidosis), ketones cannot. It is for this reason that methanol and ethylene glycol can cause an anion gap acidosis, and isopropanol cannot (Chap. 109).

The concept of functional groups, however useful, has limitations. For example, although both formic acid and oxalic acid are organic acids, they cause different patterns of organ system toxicity. Formic acid is a mitochondrial toxin and exerts effects primarily in areas (such as the retina or basal ganglia) that poorly tolerate an interruption in the energy supplied by oxidative phosphorylation. Conversely, oxalic acid readily precipitates calcium and is toxic to renal tubular cells, which accounts for the hypocalcemia and nephrotoxicity that are characteristic of severe ethylene glycol poisoning. The concept of the functional group is thus an aid to understanding chemical reactivity, but not a substitute for a working knowledge of the toxicokinetic or toxicodynamic effects of xenobiotics in living systems.

SUMMARY

- Understanding key principles of inorganic and organic chemistry provides insight into the mechanisms by which xenobiotics act.
- The periodic table forms the basis for inorganic chemistry and provides insight into the expected reactivity and to a large extent the clinical effects, of any element.
- A growing understanding of how reactive species are formed and how they interfere with physiologic processes has led to new insights in the pathogenesis and treatment of toxin-mediated diseases.
- Organic chemistry forms the basis of life, and is essential to an understanding of biochemistry and pharmacology.

13 BIOCHEMICAL AND METABOLIC PRINCIPLES

Kurt C. Kleinschmidt and Kathleen A. Delaney

Xenobiotics are compounds that are foreign to a living system. Toxic xenobiotics interfere with critical metabolic processes, causing structural damage to cells or altering their cellular genetic material. The specific biochemical sites of actions that disrupt metabolic processes are well characterized for many xenobiotics although mechanisms of cellular injury are not. This chapter reviews the biochemical principles that are relevant to an understanding of the damaging effects of toxic xenobiotics and the biotransformation enzymes and their clinical implications.

XENOBIOTIC CHARACTERISTICS AND TOXICITY

The capacity of a xenobiotic to produce injury is affected by many factors, including its absorption, distribution, elimination, site of activation or detoxification, and site of action. This section focuses on how the route of exposure and the ability to cross membranes in order to access particular organs affect toxicity.

The route of exposure to a xenobiotic may confine damage primarily to one organ, for example, pulmonary injury that follows inhalation of an irritant gas or gastrointestinal (GI) injury that follows ingestion of a caustic. Hepatocellular injury results when a toxic xenobiotic is delivered to the liver, either by the portal venous system following ingestion or by the hepatic artery carrying blood containing xenobiotics absorbed from other sites of exposure.

Various factors affect the ability of a xenobiotic to access a particular organ. For example, many potentially toxic xenobiotics fail to produce central nervous system (CNS) injury because they cannot cross the blood–brain barrier. The negligible CNS effects of the mercuric salts when compared with organic mercury compounds are related to their relative inability to penetrate the CNS. Two potent biologic xenobiotics—ricin (from *Ricinus communis*) and α -amanitin (from *Amanita phalloides*)—block protein synthesis through the inhibition of RNA polymerase. However, they result in different clinical effects because they access different tissues. Ricin has a special binding protein that enables it to gain access to the endoplasmic reticulum in GI mucosal cells, where it inhibits cellular protein synthesis and causes severe diarrhea. α -Amanitin is transported into hepatocytes by bile salt transport systems, where inhibition of protein synthesis results in cell death. The electrical charge on a xenobiotic also affects its ability to enter a cell. Unlike the ionized (charged) form of a xenobiotic, the uncharged form is often lipophilic and passes through lipid cell membranes to enter the cells. The pK_a of an acidic xenobiotic ($HA \leftrightarrow A^- + H^+$) is the pH at which 50% of the molecules are charged (A^- form) and 50% is uncharged (HA form). A xenobiotic with a low pK_a is more likely to be absorbed in an acidic environment where the uncharged form predominates.

GENERAL ENZYME CONCEPTS

The capability to detoxify and eliminate both endogenous toxins and xenobiotics is crucial to the maintenance of physiologic homeostasis. A simple example is the detoxification of cyanide, a potent cellular poison that is common in the environment and is also a product of normal metabolism. Mammals have evolved the enzyme rhodanese, which combines cyanide with thiosulfate to create the less toxic, renally excreted compound thiocyanate.⁵

Most xenobiotics have lipophilic properties that facilitate absorption across cell membranes of organs that are portals of entry into the body: the skin, GI tract, and lungs. The liver has the highest concentration of enzymes that metabolize xenobiotics. Enzymes found in the cytosol of hepatocytes that are specific for alcohols, aldehydes, esters, or amines act on many different substrates within these broad chemical classes. Enzymes that act on more lipophilic xenobiotics, including the cytochrome P450 (CYP) enzymes, are embedded in the lipid membranes of the cytosol-based endoplasmic reticulum. Microsomes are the pieces of the endoplasmic reticulum that result when cells are disrupted. When cells are mechanically disrupted and centrifuged, these membrane-bound enzymes are found in the pellet, or microsomal fraction, hence they are called microsomal enzymes. Enzymes located in the liquid matrix of cells are called cytosolic enzymes and are found in the supernatant when disrupted cells are centrifuged.¹⁸

BIOTRANSFORMATION OVERVIEW

The study of xenobiotic metabolism was established as a scientific discipline by the seminal publication of Williams in 1949.⁹³ Biotransformation is the physiochemical alteration of a xenobiotic, usually as a result of enzyme action. Most definitions also include that this action converts lipophilic substances into more polar, excretable substances.^{52,83} Most xenobiotics undergo some biotransformation, the degree of which is affected by their chemical nature. The hydrophilic nature of ionized compounds such as carboxylic acids enables the kidneys to rapidly eliminate them. Very volatile compounds, such as enflurane, are expelled promptly via the lungs. Neither of these groups of xenobiotics undergo significant enzymatic metabolism.

Biotransformation usually results in “detoxification,” a reduction in the toxicity, by the conversion to hydrophilic metabolites of the xenobiotic that can be renally eliminated.⁵² However, this is not always the case. Many parent xenobiotics are inactive and must undergo “metabolic activation,” a classic concept introduced in 1947.⁵⁴ When metabolites are more toxic than the parent xenobiotic, biotransformation has resulted in “toxification.”⁸³ Biotransformation via acetylation or methylation enhances the lipophilicity of a xenobiotic. Biotransformation is done by impressively few enzymes, reflecting broad substrate specificity. The predominant pathway for the biotransformation of an individual xenobiotic is determined by many factors, including the availability of cofactors, changes in the concentration of the enzyme caused by induction, and the presence of inhibitors. The predominant pathway is also affected by the rate of substrate metabolism, reflected by the K_m (Michaelis-Menten dissociation constant) of the biotransformation enzyme⁸³ (Chap. 9).

Biotransformation is often divided into phase I and phase II reactions, terminology first introduced in 1959.⁹⁴ Phase I reactions prepare lipophilic xenobiotics for the addition of functional groups or actually add the groups, converting them into more chemically reactive metabolites. This is usually followed by phase II synthetic reactions that conjugate the reactive products of phase I with other molecules that render them more water soluble, further detoxifying the xenobiotics and facilitating renal elimination. However, since biotransformation often does not follow this stepwise process, it has been suggested that phase I and II terminology be eliminated.³⁹ Some xenobiotics undergo only a phase I or a phase II reaction prior to elimination. Additionally, phase II reactions can precede phase I. While virtually all phase II synthesis reactions cause inactivation, a classic exception is fluoroacetate being metabolized to fluorocitrate, a potent inhibitor of the tricarboxylic acid cycle (Chap. 115).⁶⁹

Biotransformed xenobiotics cannot be eliminated until they are moved back across cell membranes, out of the cells. Membrane transporters are proteins that move agents across the membranes without altering their chemical compositions, a process called a phase III reaction because it typically occurs after biotransformation.³⁹ However, membrane transport does not always occur after phase I or II reactions. Some parent compounds are transported across membranes without any biotransformation at all.

Phase I Biotransformation Reactions

Oxidation is the predominant phase I reaction, adding reactive functional groups suitable for synthetic conjugation during phase II. These groups include hydroxyl (–OH), sulfhydryl (–SH), amino (–NH₂), aldehyde (–CHO), or carboxyl (–COOH) moieties. Noncarbon elements such as nitrogen, sulfur, and phosphorus are also oxidized in phase I reactions. Other phase I reactions include hydrolysis (the splitting of a large molecule by the addition of water that is divided among the two products), hydration (incorporation of water into a complex molecule), hydroxylation (the attachment of –OH groups to carbon atoms), reduction, dehalogenation, dehydrogenation, and dealkylation.^{52,83}

The CYP enzymes are the most numerous and important of the phase I enzymes. A common oxidation reaction catalyzed by CYP enzymes is illustrated by the hydroxylation of a xenobiotic R–H to R–OH (Fig. 13–1).²⁴ Membrane-bound flavin monooxygenase (FMO), an NADPH-dependent oxidase located in the endoplasmic reticulum, is an important oxidizer of amines and other compounds containing nitrogen, sulfur, or phosphorus.⁵²

FIGURE 13–1. A common oxidation reaction catalyzed by CYP enzymes: the hydroxylation of Drug-H to Drug-OH.

The alcohol, aldehyde, and ketone oxidation systems use predominantly cytosolic enzymes that catalyze these reactions using NADH/NAD⁺ (Fig. 13–2).^{49,83} Two classic phase I oxidation reactions are the metabolism of ethanol to acetaldehyde by alcohol dehydrogenase (ADH) followed by the metabolism of acetaldehyde to acetic acid by aldehyde dehydrogenase (ALDH). Alcohol dehydrogenase, which oxidizes many different alcohols, is found in the liver, lungs, kidneys, and gastric mucosa.⁴⁹ Women have less ADH in their gastric mucosa than men. This results in decreased first-pass metabolism of alcohol and increased alcohol absorption. Some populations, particularly Asians, are deficient in ALDH, resulting in increased acetaldehyde concentrations and symptoms of the acetaldehyde syndrome⁴⁹ (Chap. 79).

FIGURE 13–2. This is the conversion of ethanol to acetaldehyde by CYP2E1, using NADPH and oxygen, and by alcohol dehydrogenase, using NAD^+ . This illustrates how NAD and NADP can function in oxidation reactions in both their oxidized and reduced forms. Alcohol dehydrogenase has a low K_m for ethanol and is the predominant metabolic enzyme in moderate drinkers.

Oxidation Overview

Biotransformation often results in the oxidation or reduction of carbon. A substrate is oxidized when it transfers electrons to an electron-seeking (electrophilic or oxidizing) molecule, leading to reduction of the electrophilic molecule. These oxidation-reduction reactions are usually coupled to the cyclical oxidation and reduction of a cofactor, such as the pyridine nucleotides, nicotinamide adenine dinucleotide (NADH/NAD^+), or nicotinamide adenine dinucleotide phosphate ($\text{NADPH}/\text{NADP}^+$). The nucleotides alternate between their reduced (NADPH , NADH) and oxidized (NADP^+ , NAD^+) forms. Because xenobiotic oxidation is the most common phase I reaction, the newly created reduced cofactors must have a place to unload their electrons; otherwise, biotransformation ends. The electron transport chain serves as the major electron recipient.

Electrons resulting from the catabolism of energy sources are extracted primarily by NAD^+ , forming NADH . Within the mitochondria, NADH transports its electrons to the cytochrome-mediated electron transport chain. This results in the production of adenosine triphosphate (ATP), the reduction of molecular oxygen to water, and the regeneration of NAD^+ —all parts critical to the maintenance of oxidative metabolism. NADPH , created within the hexose monophosphate shunt, is used in the synthetic (anabolic) reactions of biosynthesis (especially fatty acid synthesis). NADPH is also the cofactor in the reduction of glutathione, a molecule vital to the protection of cells from oxidative damage.

The oxidation state of a specific carbon atom is determined by counting the number of hydrogen and carbon atoms to which it is connected. The more reduced a carbon, the higher the number of connections. For example, the carbon in methanol (CH_3OH) has three carbon–hydrogen bonds and is more reduced than the carbon in formaldehyde ($\text{H}_2\text{C}=\text{O}$), which has two. Carbon–carbon double bonds count as only one connection.

Cytochrome Enzymes—An Overview

Cytochromes are a class of hemoprotein enzymes whose function is electron transfer, using a cyclical transfer of electrons between oxidized (Fe^{3+}) or reduced (Fe^{2+}) forms of iron. One type of cytochrome is cytochrome P450 (CYP) whose nomenclature derives from the spectrophotometric characteristics of its associated heme molecule. When bound to carbon monoxide, the maximal absorption spectrum of the reduced CYP (Fe^{2+}) enzyme occurs at 450 nm.⁵⁹ CYP enzymes split the two oxygen atoms of an oxygen molecule, incorporating one into the substrate and one into water and thus are called mixed-function oxidases or monooxygenases. This differs from dioxygenases that incorporate both oxygen atoms into the substrate.^{59,83}

Cytochrome enzymes perform many functions. The biotransformation CYP enzymes are bound to the lipid membranes of the smooth endoplasmic reticulum. They execute 75% of all xenobiotic metabolism and most phase I oxidative biotransformations of xenobiotics.³² A second role for CYP enzymes is synthetic: biotransforming endobiotics (chemicals endogenous to the body) to cholesterol, steroids, bile acids, fatty acids, prostaglandins, and other important lipids. Cytochromes also act as electron transfer agents within the mitochondrial electron transport chain.^{33,59}

Although more than 6000 CYP genes exist in nature, the human genome project determined that the number of human CYP genes at 57.⁵⁹ CYP enzymes are categorized according to the similarities of their amino acid sequences. They are in the same “family” if they are more than 40% comparable and same “subfamily” if they are more than 55% similar. Families are designated by an Arabic numeral (n), subfamilies by a capital letter (X), and each individual enzyme by another numeral (m), resulting in the nomenclature CYPnXm for each enzyme. For example, CYP3A4 is enzyme number 4 of the CYP3 family and of the CYP3A subfamily.⁵⁶ Most xenobiotic metabolism is done by the CYP1, CYP2, and CYP3 families, with a small amount done by the CYP4 family.^{10,90} Although 15 CYP enzymes metabolize xenobiotics,⁶⁶ nearly 90% is done by 6 CYP enzymes: 1A2, 2C9, 2C19, 2D6, 2E1, and 3A4 (Table 13–1).⁵⁹

TABLE 13–1. Characteristics of Different Cytochrome P450 Enzymes^{1,10,20,23,47,57,62}

Enzyme	1A2	2C9	2C19	2D6	2E1	3A4
Percent of liver CYPs	2%	10%–20%	10%–20%	30%	7%	40%–55%
Contribution to enterocyte CYPs	Minor	Minor	Minor	Minor	Minor	70%
Organs other than liver with enzyme	Lung	Small intestine, nasal mucosa, heart	Small intestine, nasal mucosa, heart	Small intestine, kidney, lung, heart	Lung, small intestine, kidney	Much in small intestine; some in kidney, nasal mucosa, lung, stomach
Percent of metabolism of typically used drugs	2%–15%	10%–15%		25%–30%		50%–60%
Polymorphism ^a	No	Yes	Yes	Yes	No	No
Poor metabolizer						
African American	—	1%–2%	20%	2%–8%	—	—
Asian	—	1%–2%	15%–20%	>1%	—	—
White	—	1%–3%	3%–5%	5%–10%	—	—
Ultra extensive metabolizer						
Asian	—	—	—	1%	—	—
Ethiopian	—	—	—	30%	—	—
Northern Europeans	—	—	—	1%–2%	—	—
Southern Europeans	—	—	—	10%	—	—

^aEnzyme variations exist even in those listed as “No” for polymorphism.

Most CYP enzymes are found in the liver, where they comprise 2% of total microsomal protein.⁶⁶ High concentrations are also found in extrahepatic tissues, particularly the GI tract and kidney.^{20,60} The lungs,⁹⁶ heart,⁶⁴ and brain²¹ have the next highest amounts. Each tissue has a unique profile of CYP enzymes that determines its sensitivity to different xenobiotics.²⁰ The CYP enzymes in the enterocytes of the small intestine actually contribute significantly to “first-pass” metabolism of some xenobiotics.^{42,59} Corrected for tissue mass, the CYP enzyme system in the kidneys is as active as that in the liver. The activity of the renal CYP enzymes is decreased in patients with chronic kidney disease, with relative sparing of CYPs 1A2, 2C19, and 2D6 compared with 3A4 and 2C9.¹⁰

Cytochrome P450 Enzyme Specificity for Substrates

In vitro models are used to define the specificities of CYP enzymes for their substrates and inhibitors. However, activity in a test tube does not always correlate with that in a cell. These models use substrate and inhibitor concentrations that are much higher than would be encountered in vivo, and the mathematical models that extrapolate to clinically relevant processes yield conflicting results. This has resulted in discrepancies in reported substrates, inhibitors, and inducers of specific CYP enzymes.⁹²

Most CYP enzymes involved in xenobiotic biotransformation have broad substrate specificity and can metabolize many xenobiotics.³² This is fortunate because the number of xenobiotic substrates may exceed 200,000 and continues to grow.⁴⁸ Broad substrate specificity often results in multiple CYP enzymes being able to biotransform a xenobiotic. This enables the ongoing biotransformation despite an inhibition or deficiency of an enzyme. When a substrate can be biotransformed by more than one enzyme, the enzyme with the highest affinity for the substrate usually predominates at low substrate concentrations, whereas enzymes with lower affinity may be very important at high concentrations. This transition is usually concomitant with, but not dependent on, the saturation of the catalytic capacity of the primary enzyme as it reaches its maximum rate of activity.³² The K_m , which is defined as the concentration of substrate that results in 50% of maximal enzyme activity, describes this property of enzymes. For example, ADH in the liver has a very low K_m for ethanol, making it the primary metabolic enzyme for ethanol when concentrations are low.⁴⁹ Ethanol is also biotransformed by the CYP2E1 enzyme, which has a high K_m for ethanol and only functions when ethanol concentrations are high. The CYP2E1 enzyme metabolizes little ethanol in moderate drinkers but accounts for significantly more biotransformation in alcoholics. As another example, diazepam is metabolized by both CYP2C19 and CYP3A4 enzymes. However, the affinity of CYP3A4 for diazepam is so low (ie, the K_m is high) that most diazepam is metabolized by CYP2C19.³⁴

The substrate selectivity of some CYP enzymes is determined by molecular and physicochemical properties of the substrates. The CYP1A subfamily has greater specificity for planar polyaromatic substrates such as benzo[a]pyrene. The CYP2E enzyme subfamily targets low-molecular-weight hydrophilic xenobiotics, whereas the CYP3A4 enzyme has increased affinity for lipophilic compounds. Substrates of CYP2C9 are usually weakly acidic, whereas those of CYP2D6 are more basic.⁴⁸ High specificity can also result from key structural considerations such as stereoselectivity. Some xenobiotics are racemic mixtures of two stereoisomers that are substrates for different CYP enzymes and have distinct affinities for the enzymes, resulting in different rates of metabolism. For example, R-warfarin is biotransformed by CYP3A4 and CYP1A2, whereas S-warfarin is metabolized by CYP2C9.^{76,83}

The CYP enzymes that biotransform a specific xenobiotic cannot be predicted by its drug class. For example, fluoxetine and paroxetine are both major substrates and potent inhibitors of CYP2D6, but sertraline is not extensively metabolized by this enzyme and exhibits minimal interaction with other antidepressants.⁴ Most β -hydroxy- β -methylglutarylcoenzyme A (HMG-CoA) reductase inhibitors are metabolized by CYP3A4 (lovastatin, simvastatin, and atorvastatin); however, fluvastatin is metabolized by CYP2D6 and pravastatin undergoes virtually no CYP enzyme metabolism at all.⁵¹ Among angiotensin-II receptor blockers, losartan and irbesartan are metabolized by CYP2C9, whereas valsartan, eprosartan, and candesartan are not substrates for any CYP enzyme. In addition, losartan is a prodrug whose active metabolite provides most of the pharmacologic activity, whereas irbesartan is the primary active compound. For these two drugs the inhibition of CYP2C9 is predicted to have opposite effects.²⁶

Cytochrome P450 and Drug–Drug/Drug–Chemical Interactions

Adverse reactions to medications and drug–drug interactions are common causes of morbidity and mortality, the risk of which increases with the number of drugs taken (Chaps. 139 and 140). Fifty percent of adverse reactions may be related to pharmacogenetic factors.²⁸ The most significant interactions are mediated by CYP enzymes.⁵⁹ The impacts of genetic polymorphism and enzyme induction or inhibition are addressed below.

CYP enzymes are involved in many types of drug interactions. The ability of potential new drugs to induce or inhibit enzymes is an important consideration of industry. Drug development focuses on the potential of new xenobiotics to induce or inhibit other drugs or enzymes during the drug discovery phase. Various in vitro models have been created to enable this early determination.⁵⁰

Many xenobiotics interact with the CYP enzymes. St. John's wort, an herb marketed as a natural antidepressant, induces multiple CYP enzymes, including 1A2, 2C9, and 3A4. The induction of CYP3A4 by St. John's wort is associated with a 57% decrease in effective serum concentrations of indinavir when given concomitantly.⁶⁷ Xenobiotics contained in grapefruit juice, such as naringin and furanocoumarins, are both substrates and inhibitors of CYP3A4. They inhibit the first-pass metabolism of CYP3A4 substrates by inhibiting CYP3A4 activity in both the GI tract and the liver.¹⁷ Polycyclic hydrocarbons found in charbroiled meats and in cigarette smoke induce CYP1A2. Thus, for smokers who drink coffee, concentrations of caffeine, a CYP1A2 substrate, will increase following a permanent cessation of smoking.²⁴

Genetic Polymorphism

The response to xenobiotics and to coadministration of inhibitory or inducing xenobiotics is highly variable. The translation of DNA sequences into proteins results in the phenotypic expression of the genes. When a genetic mutation occurs, the changed DNA may continue to exist, be eliminated, or propagate into a polymorphism. A polymorphism is a genetic change that exists in at least 1% of the human population.^{28,59} A polymorphism in a biotransformation enzyme may change its rate of activity. The heterogeneity of CYP enzymes contributes to the differences in metabolic activity between patients.²⁸ Differences in biotransformation capacity that lead to toxicity, once thought to be “idiosyncratic” drug reactions, are likely caused by these inherited differences in the genetic complement of individuals.

The normal catalytic speed of CYP enzyme activity is called extensive. There are two major metabolizer phenotypes due to polymorphism: poor (slow) and ultraextensive (rapid).^{28,56} The CYP2C19 and CYP2D6 genes are highly polymorphic (Table 13–1). The CYP2D6 gene, which has more than 90 alleles, is associated with both ultraextensive and poor metabolism. The CYP2C19 and CYP2C9 genes are both associated with polymorphisms resulting in poor metabolizers.^{10,59}

The clinical implications of polymorphisms are vast. A prodrug may not be bioactivated because the patient is a poor metabolizer. Conversely, a drug may not reach a therapeutic concentration because the patient is an ultraextensive metabolizer.²⁸

Polymorphisms exist for enzymes other than CYP enzymes. A classic one is the inheritance of rapid or slow “acetylator” phenotypes. Acetylation is important for the biotransformation of amines ($R-NH_2$) or hydrazines (NH_2-NH_2). Slow acetylators are at increased risk of toxicity associated with the slower biotransformation of certain nitrogen-containing xenobiotics such as isoniazid, procainamide, hydralazine, and sulfonamides.⁷⁸

Polymorphic genes that code for enzymes in important metabolic pathways affect the toxicity of a xenobiotic by altering the response to, or the disposition of, the xenobiotic. An example occurs in glucose-6-phosphate dehydrogenase (G6PD) deficiency. G6PD is a critical enzyme in the hexose monophosphate shunt, a metabolic pathway located in the red blood cell (RBC) that produces NADPH, which is required to maintain RBC glutathione in a reduced state. In turn, reduced glutathione prevents hemolysis during oxidative stress.¹² In patients deficient in G6PD, oxidative stress produced by electrophilic xenobiotics results in hemolysis.

Induction of CYP Enzymes

Biotransformation by induced CYP enzymes results in either increased activity of prodrugs or enhanced elimination of drugs. Stopping an inducing agent may result in the opposite effects. Either way, maintaining therapeutic concentrations of affected drugs is difficult, resulting in either toxicity or subtherapeutic concentrations. Interestingly, not all CYP enzymes are inducible. The inducible enzymes include CYP2A, CYP2B, CYP2C, CYP2E, and CYP3A.⁵⁰

While varied mechanisms of induction exist, the most common and significant is nuclear receptor (NR)-mediated increase in gene transcription.⁵⁰ NRs are the largest group of transcription factors (proteins) that switch genes on or off.⁸⁷ They regulate reproduction, growth, and biotransformation enzymes, including CYP enzymes.⁸⁴ NRs exist mostly within the cytoplasm of cells. The CYP families 2 and 3 both have gene activation triggered through the NR pregnane X receptor (PXR) and the constitutive androstane receptor (CAR). The CYP 1A subfamily uses the aryl hydrocarbon receptor (AhR) as its NR. Ligands, molecules that bind to and affect the reactivity of a central molecule, are typically small and lipophilic, enabling them to enter cells. Many xenobiotics are ligands. Ligands bind the NRs, resulting in structural changes that enable the NR-ligand complexes to be translocated into the cell nucleus. Within the nucleus, NR-ligand complexes bind to proteins such as the retinoid X receptor (RXR), shared by the PXR and the CAR, or the AhR nuclear translocator (Arnt), or by the AhR. This new complex then interacts with specific response elements of DNA, initiating the transcription of a segment of DNA, and resulting in the phenotypic expression of the respective CYP enzyme.

The ligand-binding domain of the PXR is very hydrophobic and flexible, enabling this pocket to bind many substrates of varied sizes and reflecting why the PXR can be activated by a broad group of ligands.^{65,84} For example, xenobiotic ligands that bind the NR PXR that targets the CYP3A4 gene include rifampin, omeprazole, carbamazepine, and troleandomycin. Phenobarbital, a classic inducing xenobiotic, is a ligand that binds the CAR.⁸⁷ The induction of CYP1A subfamily enzymes is through the interaction with the NR AhR. Exogenous AhR ligands are hydrophobic, cyclic, planar molecules. Classic AhR ligands include polycyclic hydrocarbons such as 2,3,7,8-tetrachlorodibenzo-p-dioxin and benzo[a]pyrene.⁶⁵

Induction requires time to occur because it involves de novo synthesis of new proteins. Similarly, withdrawal of the inducer results in a slow return to the original enzyme concentration.⁵⁰ Polyaromatic hydrocarbons (PAHs) result in CYP1A subfamily induction within 3 to 6 hours with a maximum effect within 24 hours.⁸⁰ The inducer rifampin does not affect verapamil trough concentrations maximally until one week; followed by a two-week return to baseline steady state after withdrawal of rifampin.⁵⁰ Xenobiotics with long half-lives require longer periods to reach steady-state concentrations that maximize induction. Phenobarbital and fluoxetine, which have long half-lives, may fully manifest induction only after weeks of exposure. Conversely, xenobiotics with short half-lives, such as rifampin or venlafaxine, can reach maximum induction within days.¹⁰

Inconsistency in CYP induction exists in all organs and among individuals.^{50,65} In an in vitro study of the effects of inducing xenobiotics on 60 livers, differences in enzyme induction ranged from 5-fold for CYP3A4 and CYP2C9 up to more than 50-fold for CYP2A6 and CYP2D6.⁵⁰ The inconsistency likely results from both polymorphisms and multiple environmental factors including diet, tobacco, and pollutants.⁵⁰ There is variation in the extent to which inducers can generate new CYP enzymes. Identical dosing regimens with rifampin have resulted in induction of in vivo hepatic CYP3A4 with up to 18-fold differences between subjects.⁵⁰ There is an inverse correlation of the degree of inducibility of an enzyme and the baseline enzyme concentration. Patients with a relatively low baseline concentration of a CYP enzyme will be more inducible than those with a high baseline concentration. Interestingly, the maximum concentrations of CYP enzymes seem to be quantitatively similar among individuals, suggesting a limit to which enzymes can be induced.⁵⁰

Although the focus of this section is on CYP enzymes, it appears that all phases of xenobiotic metabolism are regulated by NRs.⁸ Also, just as genetic polymorphisms exist for CYP enzymes, they exist for NRs including the AhR, the CAR, and the PXR. This results in varied sensitivities to the ligands that complex with the NRs, ultimately resulting in differences in CYP enzyme induction.^{50,87}

Inhibition of CYP Enzymes

CYP enzyme inhibition can result in increased bioavailability of a drug or decreased bioactivation of a prodrug.⁶⁶ Inhibition of CYP enzymes is the most common cause of harmful drug-drug interactions.⁶⁶ Inhibition of CYP enzymes by coadministered xenobiotics has resulted in the removal of many medications from the market in recent years, including

terfenadine, mibefradil, bromfenac, astemizole, cisapride, cerivastatin, and nefazodone.⁹² The appendix at the end of this chapter includes a comprehensive listing of cytochrome P450 substrates, inhibitors, and inducers.

Inhibition mechanisms include irreversible (mechanism-based inhibition) and the more common reversible processes. The most common type of reversible inhibition is competitive, where the substrate and inhibitor both bind the active site of the enzyme.^{66,92} Binding is weak and is formed and broken down easily, resulting in the enzyme becoming available again. It occurs rapidly, usually beginning within hours.¹⁰ Because the degree of inhibition varies with the concentration of the inhibitor, the time to reach the maximal effect correlates with the half-life of the xenobiotic in question.¹⁰ A competitive inhibitor can be overcome by increasing the substrate concentration. Each substrate of a CYP enzyme is an inhibitor of the metabolism of all the other substrates of the same enzyme, thereby increasing their concentrations and half-lives. Reversible, noncompetitive inhibition occurs when an inhibitor binds a location on an enzyme that is not the active site, resulting in a structural change that inhibits the active enzyme site. For example, noncompetitive inhibitors of CYP2C9 include nifedipine, tranylcypromine, and medroxyprogesterone.⁷⁷ Another reversible mechanism results from competition between one xenobiotic and a metabolite of a second xenobiotic at its CYP enzyme substrate binding site. For example, the metabolites of clarithromycin and erythromycin produced by CYP3A inhibit further CYP3A activity. The effect is reversible and usually increases with repeated dosing.⁷⁷ Some reversible inhibitors bind so tightly to the enzyme that they essentially function as irreversible inhibitors.⁶⁶

Irreversible inhibitors have reactive groups that covalently, and thus permanently, bind the enzyme. They display time-dependent inhibition because the amount of active enzyme at a given concentration of irreversible inhibitor will be different depending on how long the inhibitor is preincubated with the enzyme. Because the enzyme will never be reactivated, inhibition lasts until new enzyme is synthesized.⁶⁶ One measure of inhibitor potency is the inhibitory concentration, K_i , the concentration of the inhibitor that produces 50% inhibition of the enzyme. The more potent the inhibitor, the lower the value.⁸⁰ Values below 1 $\mu\text{mol/L}$ are regarded as potent.⁶² The azole antifungals are very potent, with K_i values of 0.02 $\mu\text{mol/L}$.⁸⁰

The impact of an inhibitor is also affected by the fraction of the substrate that is biotransformed by the inhibited, target enzyme. The inhibition of a CYP enzyme will have little impact if the enzyme only metabolizes a fraction of the affected drug.⁶² Conversely, drugs that are primarily metabolized by a single CYP enzyme are more susceptible to interactions.⁶⁶ Simvastatin is mainly biotransformed by CYP3A4. The potent and specific CYP3A inhibitor itraconazole prevents its metabolism, resulting in an increased risk of rhabdomyolysis.¹

Specific CYP Enzymes

CYP1A1 and 1A2. While 1A1 is located primarily in extrahepatic tissue, 1A2 is a hepatic enzyme and is involved in the metabolism of 10% to 15% of all pharmaceuticals.^{10,50} They both are very inducible by polycyclic aromatic hydrocarbons, including those in cigarette smoke and charred food. They bioactivate several procarcinogens including benzo[a]pyrene.⁴³ Xenobiotics activated by the CYP1 enzyme family in the GI tract are linked to colon cancer.⁵⁹

CYP2C9. The CYP2 enzyme family, with its 76 alleles, is one of the most polymorphic of the CYP enzymes (Table 13–1).^{24,88} The CYP2C9 enzyme is the most abundant enzyme of the CYP2C enzyme subfamily, which with CYP2C19, comprises approximately 10% to 20% of the CYP enzymes in the liver and is involved in 15% to 20% of all drug metabolism.^{24,88} This enzyme biotransforms S-warfarin, the more active isomer of warfarin. Warfarin is one of the most commonly reported causes of adverse drug events. There is an association between slow metabolism and an increased risk of bleeding in patients taking warfarin.^{13,76}

CYP2D6. This enzyme is of historical significance because the exploration of differences in pharmacokinetics among individuals taking the antihypertensive debrisoquine was an important part of the beginning of pharmacogenetics. This enzyme is highly polymorphic, with more than 90 allelic variants.⁶³ Twenty-five percent of pharmaceuticals, including 50% of the commonly used antipsychotics, are substrates for CYP2D6.^{38,59,63} Because CYP2D6 is the only drug-metabolizing CYP enzyme that is noninducible, the polymorphisms are the primary reason for the substantial interindividual variation in enzyme activity.⁶³

CYP2E1. This enzyme comprises 7% of the total CYP enzyme content in the human liver.⁵⁸ It metabolizes small organic compounds, including ethanol, carbon tetrachloride, and halogenated anesthetics.⁸⁰ It also biotransforms low-molecular-weight xenobiotics including benzene, acetone, and N-nitrosamines.⁸⁰ Some of its substrates are procarcinogens, which are bioactivated by CYP2E1. Besides CYP1A2, this is the only other CYP enzyme linked to cancer.⁵⁹ The assessment for a relationship between CYP2E1 and cancer is intense because many of its substrates are environmental xenobiotics. The induction of CYP2E1 is associated with increased liver injury by reactive metabolites of carbon tetrachloride and vinyl chloride (Chap. 23).³⁰ During the metabolism of substrates that include carbon tetrachloride, ethanol, acetaminophen (APAP), aniline, and N-nitrosomethylamine, CYP2E1 actively produces free radicals and other reactive metabolites

associated with adduct formation and lipid peroxidation (Chaps. 9 and 35).¹⁴ CYP2E1 is inhibited by acute elevations of ethanol, an effect illustrated by the acute administration of ethanol inhibiting the metabolism of APAP.³⁰ The chronic ingestion of ethanol hastens its own metabolism through CYP2E1 induction.

CYP3A4. CYP3A4 is the most abundant CYP in the human liver, comprising 40% to 55% of the mass of hepatic CYP enzymes.^{10,24} The CYP3A4 enzyme is the most common one found in the intestinal mucosa and is responsible for much first-pass drug metabolism.¹⁰ It is involved in the biotransformation of 50% to 60% of all pharmaceuticals.^{58,97} It has broad substrate specificity because it accommodates large lipophilic substrates and can adopt multiple conformations. It can even simultaneously fit two relatively large compounds (ketoconazole, erythromycin) in its active site.⁷⁵

Methadone, extensively metabolized by CYP3A4, is associated with many examples of adverse drug interactions.⁴¹ Torsade de pointes is reported in methadone patients who are also exposed to CYP3A4 inhibitors including ciprofloxacin,⁵⁷ itraconazole,⁶¹ and the antiretrovirals atazanavir and ritonavir.²³ Ketoconazole inhibits CYP3A4, causing a 15-fold to 72-fold increase in serum concentrations of terfenadine.⁵⁹ Bioflavonoids in grapefruit juice decrease metabolism of some substrates by 5-fold to 12-fold.^{10,59} The CYP3A4 enzyme does not exhibit significant genetic polymorphism; however, there are large interindividual variations in enzyme concentrations that can affect metabolic rates.⁹⁷

Phase II Biotransformation Reactions

Phase II biotransformation reactions are synthetic, catalyzing the conjugation of products of phase I reactions or xenobiotics with endogenous molecules that are generally hydrophilic. Conjugation usually terminates the pharmacologic activity of xenobiotics and greatly increases their water solubility and excreatability.^{52,83,95} Conjugation occurs most commonly with glucuronic acid, sulfates, and glutathione. Less common phase II reactions include conjugation with amino acids such as glycine, glutamic acid, and taurine as well as acetylation and methylation.

Glucuronidation is the most common phase II synthesis reaction.⁵² Glucuronyl transferase has relatively low substrate affinity but it has high capacity at higher substrate concentrations.⁸³ The glucuronic acid, donated by uridine diphosphate glucuronic acid, is conjugated with the nitrogen, sulfhydryl, hydroxyl, or carboxyl groups of substrates. Smaller conjugates usually undergo renal elimination, whereas larger ones undergo biliary elimination.⁴⁸

Sulfation complements glucuronidation because it is a high-affinity but low-capacity reaction that occurs primarily in the cytosol. For example, the affinity of sulfate for phenol is very high (the K_m is low), so that when low doses of phenol are administered, the predominant excretion product is the sulfate ester. Because the capacity of this reaction is readily saturated, glucuronidation becomes the main method of detoxification when high doses of phenol are administered.^{52,95} Sulfate conjugates are highly ionized and very water soluble. Of note, sulfation is reversible by the action of sulfatases within the liver. The resultant metabolites may be resulfated, and the cycle may repeat itself further.⁹⁵

Glutathione S-transferases are important because they catalyze the conjugation of the tripeptide glutathione (glycine-glutamate-cysteine, or GSH) with a diverse group of reactive, electrophilic metabolites of phase I CYP enzymes. The reactive compounds initiate an attack on the sulfur group of cysteine, resulting in conjugation with GSH that detoxifies the reactive metabolite. Of the three phase II reactions addressed, hepatic concentrations of glutathione by far account for the greatest amount of cofactors used. Although intracellular glutathione is difficult to deplete, when it does occur, severe hepatotoxicity often follows.⁹⁵ Some GSH conjugates are directly excreted. More commonly, the glycine and glutamate residues are cleaved and the remaining cysteine is acetylated to form a mercapturic acid conjugate that is readily excreted in the urine. A familiar example of this detoxification is the avid binding of N-acetyl-p-benzoquinoneimine (NAPQI), the toxic metabolite of APAP, by glutathione.^{4,9}

As with the CYP enzymes, many phase II enzymes are inducible. For example, UDP-glucuronosyltransferase, which performs glucuronidation, is inducible via the PXR, CAR, and AhR nuclear receptors after binding with rifampin, phenobarbital, and PAHs, respectively. Its activity varies 6-fold to 15-fold in liver microsomes.⁸⁷

Membrane Transporters

Although the focus on drug disposition has traditionally been on biotransformation, membrane transporter proteins greatly impact drug disposition.³⁵ Transporter proteins mediate the cellular uptake and efflux of endogenous compounds and xenobiotics.⁹⁸ Their baseline physiologic role is to transport sugars, lipids, amino acids, and hormones so as to regulate cellular solute and fluid balance. Biotransformation cannot occur unless xenobiotics are taken up into the cells via transport proteins. After xenobiotics have undergone phase I and II metabolism, the metabolites undergo transport protein mediated efflux from the cell, an action that has been called phase III metabolism.³⁹

The transport proteins that are most relevant to xenobiotic uptake and efflux are those mediating the efflux from the apical (luminal) membrane of enterocytes (P-glycoprotein), the uptake from the portal venous blood into the hepatocytes, the efflux from the hepatocytes via the canalicular membrane into the bile, the uptake into renal proximal tubular cells, and

the efflux from renal proximal tubular cells into urine.⁹⁸ Drug disposition is facilitated or prevented by the transport proteins.⁴⁴

Most transporters are in the adenosine triphosphate binding cassette (ABC) family of transmembrane proteins that use energy from ATP hydrolysis.^{11,35} This family includes the P-glycoprotein family. Some transporters move substrates both into and out of cells. Organs important for drug disposition have multiple transporters that have overlapping substrate capabilities, a redundancy that enhances protection. In the small intestine, P-glycoprotein is important because it can actively extrude xenobiotics back into the intestinal lumen.¹¹ The degree of phenotypic expression of P-glycoprotein affects the bioavailability of many xenobiotics, including paclitaxel, digoxin, and protease inhibitors. Hepatocyte efflux transporters move biotransformed xenobiotics into bile. Transporters in endothelial cells of the blood–brain barrier prevent CNS entry of substrate xenobiotics.^{11,35}

As with biotransformation enzymes and nuclear receptors, membrane transporters may also be inhibited or induced. Digoxin, a high-affinity substrate for P-glycoprotein, has increased bioavailability when administered with P-glycoprotein inhibitors such as clarithromycin or atorvastatin.³⁵ Loperamide is a substrate for P-glycoprotein that limits its intestinal absorption or CNS entry. Coadministration with quinidine, a P-glycoprotein inhibitor, results in increased opioid CNS effects of loperamide.³⁵ As with the biotransformation enzymes, polymorphisms exist for membrane transporters. However, the clinical significance of these is not clear.¹⁶

MECHANISMS OF CELLULAR INJURY

Ideally and commonly, potentially toxic metabolites produced by phase I reactions are detoxified during phase II reactions. However, detoxification does not always occur. This section reviews mechanisms of cellular injury related to xenobiotic biotransformation.

Synthesis of Toxins

Sometimes a xenobiotic is mistaken for an endogenous substrate by synthetic enzymes that biotransform it into an injurious compound. The incorporation of the rodenticide fluoroacetate into the tricarboxylic acid cycle is an example of this mechanism of toxic injury (Fig. 13–3).⁶⁹ Another example is illustrated by analogs of purine or pyrimidine bases that are phosphorylated and inserted into growing DNA or RNA chains, resulting in mutations and disruption of cell division. This mechanism is used therapeutically with 5-fluorouracil (5-FU), an antitumor, pyrimidine base analog. When phosphorylated to 5-fluoro-dUTP and incorporated into growing DNA chains, it causes structural instability of the cellular DNA and inhibits tumor growth.⁷³

FIGURE 13–3. Pyruvate is converted to acetylcoenzyme A (acetyl-CoA), which enters the Krebs cycle as shown. Reducing equivalents, in the form of NADH and FADH, donate electrons to a chain of cytochromes beginning with NADH dehydrogenase. These reactions “couple” the energy released during electron transport to the production of ATP. Ultimately, electrons combine with oxygen to form water. The sites of action of xenobiotics that inhibit oxidative metabolism are shown. The sites where thiamine functions as a coenzyme are also illustrated. DH = dehydrogenase.

Injury by Metabolites of Biotransformation

Many toxic products result from metabolic activation (Table 13–2).⁴⁰ The CYP enzymes most associated with bioactivation are 1A1, 1B1, 2A6, and 2E1, whereas 2C9 and 2D6 yield little toxic activation.³²

TABLE 13–2. Examples of Xenobiotics Activated to Toxins by Human Cytochrome P450 Enzymes

<i>CYP Substrate</i>	<i>Toxicity</i>	<i>Enzyme</i>
1A1	Benzo[a]pyrene (PAH)	IARC Group 1
1A2	APAP	Hepatotoxicity
	Aflatoxin B (<i>Aspergillus</i> mycotoxin)	IARC Group 1
	2-Naphthylamine (azo dye production)	IARC Group 1
	NNK (nitrosamine in tobacco)	IARC Group 1
	N-Nitrosodiethylamine (gas and lubricant additive, copolymer softener)	IARC Group 2A
2B6	Chrysene (PAH)	IARC Group 2B
	Cyclophosphamide	IARC Group 1
2C 8,9	Phenytoin	IARC Group 2B
	Valproic acid	Hepatotoxicity
2D6	NNK (nitrosamine in tobacco)	IARC Group 1
2F1	APAP	Hepatotoxicity
	3-Methylindole (in perfumes, cigarettes for flavor)	Pneumotoxicity
	Valproic acid	Hepatotoxicity
2E1	APAP	Hepatotoxicity
	Acrylonitrile	IARC Group 2B
	Benzene	IARC Group 1
	Carbon tetrachloride	IARC Group 2B
	Chloroform	IARC Group 2B
	Ethylene dibromide (former gas additive and fumigant)	IARC Group 2A
	Ethyl carbamate (former antineoplastic)	IARC Group 2A
	Halothane	Hepatotoxicity
	Methylene Chloride	IARC Group 2B
	N-Nitrosodimethylamine (formerly in rocket fuel)	IARC Group 2A
	Styrene	IARC Group 2A
	Trichloroethylene	IARC Group 2A
	Vinyl chloride	IARC Group 1
3A4	APAP	Hepatotoxicity
	Aflatoxin B ₁ (<i>Aspergillus</i> mycotoxin)	IARC Group 1
	Chrysene (PAH)	IARC Group 2B
	Cyclophosphamide	IARC Group 1
	1-Nitropyrene (PAH)	IARC Group 2B
	Senecionine (pyrrolizidine alkaloid)	Hepatotoxicity
	Sterigmatocystin (<i>Aspergillus</i> mycotoxin)	IARC Group 2B

Group 1 = known carcinogen; Group 2A = probable carcinogen; Group 2B = possible carcinogen; IARC = International Agency for Research on Cancer of the World Health Organization; PAH = polycyclic aromatic hydrocarbon.

Highly reactive metabolites exert damage at the site where they are synthesized; reacting too quickly with local molecules to be transported elsewhere. This commonly occurs in the liver, the major site of biotransformation of xenobiotics^{31,79} (Chap. 23). However, metabolism in the lungs, skin, kidneys, GI tract, and nasal mucosa can also create toxic metabolites that cause local injury.^{9,46} Overdoses of APAP lead to excessive hepatic production of the highly reactive electrophile NAPQI, which initiates a damaging covalent bond with hepatocytes⁴ (Chap. 35). Acute renal tubular necrosis also occurs in patients with overdose of APAP, attributed to its biotransformation by prostaglandin H synthase within renal

tubular cells to a highly reactive semiquinoneimine.^{22,91}

Monoamine oxidases (MAOs) are mitochondrial enzymes present in many tissues. They oxidize many amines, including dopamine, epinephrine, and serotonin, and xenobiotics such as primaquine and haloperidol. The metabolic activity of MAOs was responsible for the outbreak of parkinsonism associated with the use of methylphenyltetrahydropyridine (MPTP), an unintended by-product of attempts to synthesize a “designer” analog of meperidine, methylphenylpropionoxypiperidine (MPPP). After crossing the blood–brain barrier, MPTP is biotransformed by MAO in glial cells to methylphenyldihydropyridine (MPDP⁺), which is converted to MPP⁺. The MPP⁺ is subsequently taken up by specific dopamine transport systems into dopaminergic neurons in the substantia nigra, resulting in inhibition of oxidative phosphorylation and subsequent neuronal death.²⁹

Free Radical Formation

Within an atom, it is energetically favorable for electrons to exist in pairs or as a part of a chemical bond. An element or compound with an unpaired electron, called a radical or free radical, is highly reactive and short lived. It rapidly seeks other species in order to obtain another electron. Radicals include the superoxide anion O₂^{•−}, which is produced by adding an electron to O₂, and the highly reactive hydroxyl radical HO•, which is produced by splitting the H₂O₂ molecule into two equal halves. The H₂O₂ molecule itself is reactive and is also associated with injury. The superoxide and hydroxyl radicals react with other molecules in order to stabilize themselves; however, by taking an electron in order to do so, they generate new free radical species, potentially initiating a chain reaction. The production of radicals is a normal occurrence for which the human body has defense mechanisms. However, some xenobiotics promote the formation of reactive oxidant species to the extent that antioxidant mechanisms are overwhelmed, a condition called oxidative stress. Oxidizing species are called such because, by reducing themselves by taking away electrons, they oxidize the species from which they took the electrons.⁶

Although oxidative stress may result in oxidative damage to nucleic acids and proteins, other classic targets are polyunsaturated fatty acids (PUFAs) in cellular membranes, resulting in lipid peroxidation (the oxidative destruction of lipids). This attack removes the particularly reactive hydrogen atom, with its lone electron, from a methylene carbon of a PUFA, leaving an unpaired electron and causing the formation of a lipid radical. This lipid radical attacks other PUFAs, initiating a chain reaction that destroys the cellular membrane. Membrane degradation products initiate inflammatory reactions in the cells, resulting in further damage.^{6,79}

Molecular oxygen (O₂) has a lone pair of electrons in its orbit. Because oxygen is a relatively weak univalent electron acceptor (and most organic molecules are weak univalent electron donors), oxygen cannot efficiently oxidize amino acids and nucleic acids. However, the unpaired electrons of O₂ readily interact with the unpaired electrons of transition metals and organic radicals. Metals frequently catalyze the creation of oxygen free radicals. Figure 13–4 reflects the typical steps in the formation of a hydroxyl radical. The damaging effects of the free radicals are decreased by reaction with antioxidants such as ascorbate, tocopherols, and glutathione.⁵² Deficiencies of antioxidants, especially glutathione, are associated with increased oxidative damage. Free radicals are also neutralized by several enzymes, including peroxidase, superoxide dismutase, and catalase.

FIGURE 13–4. Hydroxyl radical formation. (1) First is the addition of an electron to O₂ to create the superoxide ion. (2) Then the very reactive superoxide combines with hydrogen and another electron to produce hydrogen peroxide. (3) Finally, in the presence of a metal ion catalyst such as iron, hydrogen peroxide undergoes various reactions to produce the hydroxyl radical. The dot in these formulas represents an unpaired electron, the hallmark of a free radical.^{37,52}

The ethanol-inducible CYP2E1 enzyme produces significant amounts of superoxide and peroxide free radicals, and, in the presence of iron, hydroxyl free radicals that readily initiate lipid peroxidation. This has been studied extensively in models of the metabolism of carbon tetrachloride, ethanol, and APAP.¹⁹ The formation of free radicals is implicated in the pulmonary injury caused by paraquat, the myocardial injury caused by doxorubicin, and the liver injury caused by carbon tetrachloride.^{55,70} Paraquat reacts with NADPH to form a pyridinyl free radical, which, in turn, reacts with oxygen to generate the superoxide anion radical. Doxorubicin is metabolized to a semiquinone free radical in the cardiac mitochondria, which, in the presence of oxygen, forms a superoxide anion radical that initiates myocardial lipid

peroxidation.⁵⁵ Carbon tetrachloride (CCl_4) is metabolized to the trichloromethyl radical ($\cdot\text{CCl}_3$) that binds covalently to cellular macromolecules. In the presence of oxygen, this is converted to the trichloromethylperoxyl radical ($\cdot\text{CCl}_3\text{O}_2$) that can initiate lipid peroxidation (Fig. 13–5).⁷¹ See Chap. 108 for a more extensive discussion.

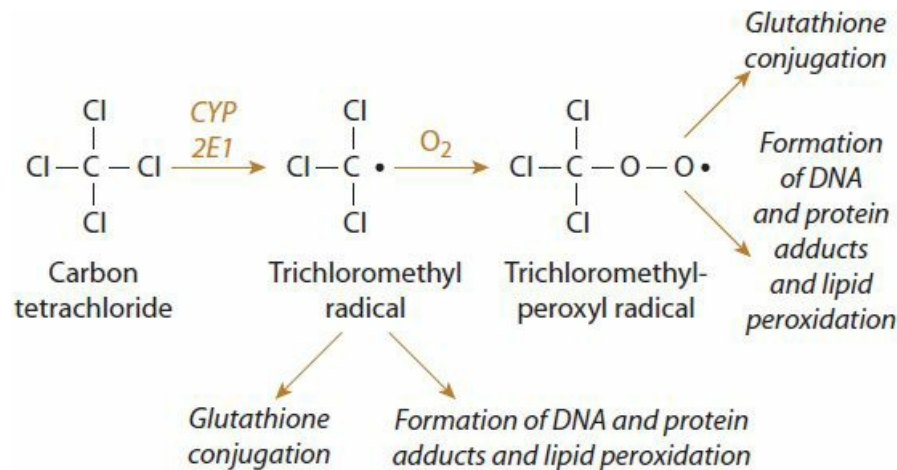

FIGURE 13–5. This is carbon tetrachloride metabolism by the hepatocyte. Under hypoxic conditions, the CCl_3 radical is the predominant species formed. At higher oxygen tensions, the CCl_3 radical is oxidized to the $\text{CCl}_3\text{OO}\cdot$ radical, which is more readily detoxified by glutathione. Both free radicals bind to hepatocytes and cause cellular injury.

CRITICAL BIOCHEMICAL PATHWAYS AND XENOBIOTICS THAT AFFECT THEM

Energy metabolism is the foundation of cellular function. It provides high-energy fuel, predominantly in the form of ATP, for all energy-dependent cellular processes such as synthesis, active transport, and maintenance of electrolyte balance and membrane integrity. Numerous pathways interconnect glycogen, fat, and protein reserves in many tissues that store and retrieve ATP and glucose. The brain and RBCs are entirely dependent on glucose for energy production, while other tissues can also use ketone bodies and fatty acids to synthesize ATP. Rapid cell death occurs if the production or use of ATP is inhibited, thus the goal of many metabolic processes is the production and mobilization of cellular energy.

Catabolic pathways, those that break down molecules into smaller units enabling the production of cellular energy, include glycolysis, the citric acid (tricarboxylic acid, or Krebs) cycle, and oxidative phosphorylation via the electron transport chain. Glycolysis produces small amounts of ATP through the anaerobic metabolism of glucose. Pyruvate, the end product of glycolysis, yields far more ATP when it is converted to acetylcoenzyme A (acetyl-CoA) and “processed” in the citric acid cycle (Fig. 13–3). Fat and protein yield their energy through their conversion to acetyl-CoA and other intermediates of the citric acid cycle. The citric acid cycle and oxidative phosphorylation, via the electron transport chain, result in most ATP synthesis. Oxidative phosphorylation disposes of electrons or “reducing equivalents” and converts their energy to ATP. A lack of oxygen stops the electron transport chain and ATP production. Oxidative metabolism is highly energy efficient, producing 36 moles of ATP for each mole of glucose metabolized, compared to the 2 moles of ATP produced by anaerobic glycolysis. The following sections review the basics of cellular energy metabolism and several important xenobiotics that affect these critical metabolic functions (Table 13–3).^{24,45}

TABLE 13–3. Inhibitors of Glucose Metabolism and ATP Synthesis

<i>Step/Location</i>	<i>Action</i>	<i>Examples</i>
Glycolysis	Inhibits NADH production	Iodoacetate (at GAPDH) NO ⁺ (at GAPDH)
	Bypasses ATP producing step	Arsenate, As ³⁺
Gluconeogenesis	Inhibits NADH production	4-(Dimethylamino)phenol <i>p</i> -benzoquinone Hypoglycin A
Fatty acid metabolism	Inhibits NADH production	Aflatoxin Amiodarone Hypoglycin Perhexiline Protease inhibitors Salicylates Tetracycline Valproic acid
Citric Acid Cycle	Inhibits NADH production	Arsenite, As ³⁺ <i>p</i> -Benzoquinone Fluoroacetate
Electron-transport chain at complex I	Inhibits electron transport	MPP ⁺ Paraquat Rotenone
Electron-transport chain at complex III	Inhibits electron transport	Antimycin-A Fusiculosin Cations: Zn ²⁺ , Hg ²⁺ , Cu ²⁺ , and Cd ²⁺ Substituted phenols (pentachlorophenol and dinitrophenol) (also uncouplers)

Electron-transport chain at complex IV	Inhibits electron transport	Azide Carbon monoxide Cyanide Formate Hydrogen sulfide Nitric oxide Phosphine Protamine
Electron-transport chain at ATP synthase	Inhibits ATP production	Arsenate, As^{3+} Mycotoxins (numerous, including oligomycin) Organic chlorines (DDT and chlordane) Organotin (cyhexatin) Paraquat
Mitochondria ADP/ATP antiporter	Disrupts the movement of ADP into and ATP out of the mitochondria at the ADP/ATP antiporter	Atractyloside DDT Free fatty acids
Mitochondria inner membrane	Uncouples oxidative phosphorylation by disrupting the proton gradient → stops proton flow at ATP synthase → stops ATP synthesis	Substituted phenols (pentachlorophenol and dinitrophenol) Lipophilic amines (amiodarone, perhexiline, buprenorphine) Benzonitrile Thiadiazole herbicides NSAIDs with ionizable groups (salicylates, diclofenac, indomethacin, piroxicam) Valinomycin Chlordane
Mitochondria inner membrane	Diverts electrons to alternate pathways (vs. to the electron-transport chain)	Doxorubicin MPP ⁺ Naphthoquinones (menadione) N-nitrosoamines Paraquat

GAPDH = glyceraldehyde 3-phosphate dehydrogenase; MPP⁺ = 1-methyl-4-phenylpyridinium.

Glycolysis

Glycolysis is the first biochemical pathway in the metabolism of glucose. Other sugars enter this pathway after conversion to glycolytic intermediates (Fig. 13–6). The glycolytic process converts one molecule of glucose to two of pyruvate plus two molecules of ATP plus two molecules of NADH. Pyruvate may follow many paths. Under anaerobic conditions, the two pyruvate molecules produced from one glucose molecule are reduced by lactate dehydrogenase to two lactate molecules in an NADH-requiring step that regenerates NAD^+ . Thus, anaerobic glycolysis yields two molecules of lactate plus two molecules of ATP. When NAD^+ and oxygen are available, pyruvate is transported from the cytosol into the mitochondria where it enters the citric acid cycle by being converted by pyruvate decarboxylase to acetyl-CoA (Fig. 13–3).^{24,45} In energy-rich conditions, pyruvate is used in fatty acid synthesis, whereas in energy-poor situations, it is used in gluconeogenesis.

FIGURE 13–6. During glycolysis, the anaerobic metabolism of one mole of glucose to two moles of pyruvate results in the net production of two moles of ATP. Arsenate (As^{5+}) results in the creation of an unstable intermediary that bypasses a step that typically creates one of those moles of ATP. Pyruvate kinase and phosphofructokinase, the enzymes whose activities are regulated by glucagon via cyclic adenosine monophosphate–dependent phosphokinase, are shown.

Arsenate (As^{5+}) affects the glycolytic step where 3-phosphoglyceraldehydeshydrogenase (3-PGA) catalyzes the oxidation of glyceraldehyde-3-phosphate to 1,3-diphosphoglycerate, a reaction that preserves a high-energy phosphate bond used to synthesize ATP in the next step of glycolysis (Fig. 13–6).³⁶ Arsenate acts as an analog of phosphate at this step, resulting in an unstable arsenate intermediate that is rapidly hydrolyzed to 3-phosphoglycerate. While glycolysis continues, there is the loss of ATP synthesis because 1,3 biphosphoglycerate is not made.³⁶

Citric Acid Cycle

The citric acid cycle uses acetyl-CoA derived from glycolysis, fat, or protein to regenerate NADH from NAD^+ . The cycle is a major source of electrons (in the form of NADH) and is critical to the aerobic production of ATP (Fig. 13–3). Each acetyl-CoA molecule that is oxidized within the citric acid cycle ultimately forms one molecule each of CO_2 and guanosine triphosphate (GTP), and more importantly, three molecules of NADH and one molecule of reduced flavin adenine dinucleotide (FADH_2), which enter the electron transport chain, producing a total of 12 molecules of ATP. In addition, the citric acid cycle provides important intermediates for amino acid synthesis and for gluconeogenesis.⁴⁵

Various xenobiotics inhibit the citric acid cycle. The rodenticides, sodium fluoroacetate and fluoroacetamide, are combined with coenzyme A, CoASH, to create fluoroacetyl CoA (FACoA). The FACoA substitutes for acetyl CoA, entering the TCA cycle by condensation with oxaloacetate to form fluorocitrate. Fluorocitrate metabolism results in a metabolite that blocks aconitase within the cycle, resulting in citrate accumulation and the termination of oxidative metabolism (Fig. 13–3) (Chap. 115).

Thiamine is an important cofactor for two citric acid cycle enzymes: the conversion of pyruvate to acetyl-CoA by pyruvate decarboxylase and for the conversion of α -ketoglutarate to succinyl-CoA by α -ketoglutarate dehydrogenase (Fig. 13–3).²⁴ The life-threatening effects of thiamine deficiency are likely related to impairment of these enzyme functions (Antidotes in Depth: A24). Arsenite (As^{3+}) inhibits these thiamine-dependent enzymes within the citric acid cycle.⁶⁹

The Electron Transport Chain

The electron transport chain is the location where the “phosphorylation” of oxidative phosphorylation occurs. Oxidative phosphorylation is the creation of high-energy bonds by phosphorylation of ADP to ATP, “coupled” to the transfer of electrons from reduced coenzymes to molecular oxygen via the electron transport chain. The success of aerobic metabolism requires the disposal of electrons within NADH and FADH, generated by oxidative metabolism within glycolysis and the citric acid cycle. The electron transport chain consists of a series of cytochrome–enzyme complexes within the inner mitochondrial membrane (Fig. 13–3). Within these complexes, NADH is split into $\text{NAD}^+ + \text{H}^+ + \text{two electrons}$ at complex I at the beginning of the chain while FADH_2 is split into $\text{FADH} + \text{H}^+ + \text{two electrons}$ at complex II. These reactions have two results. First, the regenerated NAD^+ and FADH are recycled back to the citric acid cycle, enabling oxidative metabolism to continue. Second, these actions provide the energy required to pump protons (H^+) from the mitochondrial matrix into the intermembrane space. This action causes the matrix to become relatively alkaline compared to the now acidified intermembrane space and the creation of a proton gradient across the inner mitochondrial membrane. The final step in the electron flow of oxidative phosphorylation is the reduction of molecular oxygen to water by complex IV, cytochrome a-a_3 (Fig. 13–3).^{24,45} This hydrogen ion gradient provides the energy needed to create the high-energy bonds of ATP at complex V.

Mitochondria oxidize substrates, consume oxygen, and make ATP. Xenobiotics that interrupt oxidative phosphorylation impair ATP production either by inhibiting specific electron chain complexes or by acting as “uncouplers.” Both of these mechanisms result in rapid depletion of cellular energy stores, followed by failure of ATP-dependent active transport pumps, loss of essential electrolyte gradients, and increases in cell volume.²⁵

Inhibitors of specific cytochromes block electron transport and cause an accumulation of reduced intermediates proximal to the site of inhibition. This stops the regeneration of oxidized substrates for the citric acid cycle, particularly NAD^+ and FADH, further impairing oxidative metabolism. Cyanide, carbon monoxide, and hydrogen sulfide block the cytochrome a-a_3 –mediated reduction of O_2 to H_2O . The very dramatic clinical effects of these exposures illustrate the importance of aerobic metabolism (Chap. 126). Other xenobiotics are less commonly associated with inhibition of the electron transport chain (Table 13–3).^{85,89}

Severe metabolic acidosis is a clinical manifestation of xenobiotics that inhibit aerobic respiration. This metabolic acidosis is primarily caused by the accumulation of protons in the mitochondrial matrix that are not used in the production of ATP. While lactic acid accumulates, it is only a marker for metabolic acidosis associated with the impairment of oxidative metabolism.⁷⁴

Xenobiotics that uncouple oxidative phosphorylation, like inhibitors of the electron transport chain, reduce ATP synthesis. However, with uncouplers, protons continue to be pumped into the intermembrane space, electrons continue to flow down the chain to reduce oxygen, and substrate consumption continues. Uncouplers dissipate the proton gradient across the mitochondrial inner membrane by allowing the protons to cross back into the mitochondrial matrix. Since it is the proton gradient that drives the production of ATP at complex V, ATP production is reduced. Thus, oxygen consumption is “uncoupled” from ATP production. The redox energy created by electron transport that cannot be coupled to ATP synthesis is released as heat. Various xenobiotics uncouple ATP synthesis (Table 13–3). A classic one is dinitrophenol, used in the past as an herbicide and as a weight-loss product (Chap. 42). Xenobiotics that are capable of carrying hydrogen ions across membranes are generally lipophilic weak acids. These xenobiotics must have an acid-dissociable group to carry the proton and a bulky lipophilic group to cross a membrane.⁴⁷ Dinitrophenol is able to carry its proton from the cytosol into the more alkaline mitochondrial matrix where it dissociates, acidifying the matrix and destroying the proton gradient across the inner mitochondrial membrane. Interestingly, the phenolate anion of dinitrophenol is relatively lipophilic and can cross back out to the cytosol where it gains a new proton and starts the process over again. Long-chain fatty acids uncouple oxidative phosphorylation by a similar mechanism.^{47,89} Fatal exposures to dinitrophenol and to pentachlorophenol, a wood preservative, are associated with severe hyperthermia attributed to heat generation by uncoupled oxidative phosphorylation.⁶⁸ The hyperthermia and acidosis associated with severe salicylate poisoning are attributed to its uncoupling of oxidative phosphorylation.⁸¹

Hexose Monophosphate Shunt

The hexose monophosphate shunt provides the only source of cellular NADPH. NADPH is used in biosynthetic reactions, particularly fatty acid synthesis, and is an important source of reducing power for the maintenance of sulfhydryl groups that protect the cell from free radical injury.^{7,37} As noted earlier, G6PD is a key enzyme in the pathway (Fig. 13–7). Reduced glutathione, which is quantitatively the most important antioxidant in cells, depends on the availability of NADPH. RBCs are especially vulnerable to deficiency of NADPH, which results in hemolysis during oxidative stress.

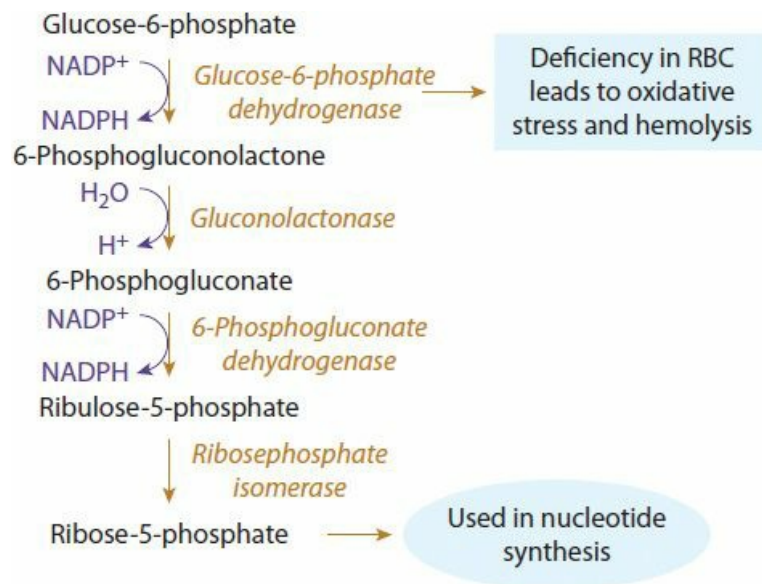

FIGURE 13–7. The oxidation reactions of the hexose monophosphate shunt are an important source of NADPH for reductive biosynthesis and for protection of cells against oxidative stress. Deficiency of glucose-6-phosphate dehydrogenase, the first enzyme in the pathway, may result in red blood cell (RBC) hemolysis during oxidative stress.

Another manifestation of oxidative stress in RBCs is the oxidation of the iron in hemoglobin from Fe^{2+} to Fe^{3+} , producing methemoglobin that occurs both spontaneously and as a response to xenobiotics such as nitrites and aminophenols. Because most reduction of methemoglobin is done by NADH-dependent methemoglobin reductase, which is not deficient in persons who lack G6PD, such persons do not develop methemoglobinemia under normal circumstances. However, when oxidative stress is severe and methemoglobinemia develops, people who have G6PD deficiency have limited ability to use the alternative NADPH-dependent methemoglobin reductase ([Chap. 127](#)).⁸⁶

Gluconeogenesis

Gluconeogenesis facilitates the conversion of amino acids and intermediates of the citric acid cycle to glucose. It occurs primarily in the liver but also in the kidney. It is an important source of glucose during fasting and enables maintenance of glycogen stores. Most of the steps in the synthesis of glucose from pyruvate are simply the reverse of glycolysis, with three irreversible exceptions: (1) the conversion of glucose-6-phosphate to glucose; (2) the conversion of fructose-1,6-diphosphate to fructose-6-phosphate; and (3) the synthesis of phosphoenolpyruvate from pyruvate. The synthesis of phosphoenolpyruvate from pyruvate is especially complex. Pyruvate is first converted to oxaloacetate within the mitochondria; then to malate, which is transported out of the mitochondria and converted in the cytosol back to oxaloacetate; and then to phosphoenolpyruvate ([Fig. 13–8](#)). Certain amino acids—notably alanine, glutamate, and aspartate—are readily converted to citric acid cycle intermediates and can be used in the synthesis of glucose through this cycle.⁴⁵ Glycerol, produced by the breakdown of triglycerides in adipose tissue, is another substrate for gluconeogenesis.

FIGURE 13–8. Gluconeogenesis reverses the steps of glycolysis, with the exception of the bypass of the three irreversible steps shown. The step from pyruvate to phosphoenolpyruvate involves both cytosolic and mitochondrial reactions that use ATP. Hypoglycin A inhibits the intramitochondrial conversion of oxaloacetate to malate by depleting NADH through interference with β -oxidation of fatty acids. Ethanol decreases cytosolic supplies of NAD^+ .

The regulation of gluconeogenesis is opposite to that of glycolysis, stimulated by glucagon and catecholamines but inhibited by insulin. Gluconeogenesis requires the cytosolic NAD^+ and mitochondrial NADH. It is impaired by processes that increase the cytosol-reducing potential as measured by the cytosol NADH/NAD^+ ratio (see discussion below).

A number of xenobiotics impair gluconeogenesis, resulting in hypoglycemia when glycogen stores are depleted (Table 13–3). Hypoglycin A, an unusual amino acid found in unripe ackee fruit that is the cause of Jamaican vomiting sickness, produces profound hypoglycemia.⁸¹ Its metabolite methylenecyclopropylacetic acid (MCPA) indirectly inhibits gluconeogenesis by blocking the oxidation of long-chain fatty acids, an important source of NADH in mitochondria. It also inhibits the metabolism of several glycogenic amino acids, including leucine, isoleucine, and tryptophan, and blocks their entrance into the citric acid cycle. MCPA may also prevent the transport of malate out of the mitochondria.^{72,81,82} Hypoglycemia also occurs in fasting patients with elevated ethanol concentrations.^{3,27,46} This is likely a result of the impairment of gluconeogenesis by the increased cytosolic $\text{NADH}:\text{NAD}^+$ ratio associated with the metabolism of ethanol. This inhibits the two cytosolic steps that require NAD^+ —the conversions of lactate to pyruvate and of malate to oxaloacetate.^{2,46}

Fatty Acid Metabolism

Fatty acid metabolism occurs primarily in hepatocytes. Fatty acids mobilized in adipose tissue enter hepatocytes by passive diffusion. Fatty acid synthesis is stimulated by insulin and inhibited by glucagon and epinephrine. Acetyl-CoA is the primary building block of free fatty acids (FFAs). In energy-replete cells, fatty acids are combined with glycerol phosphate to form triacylglycerol (triglycerides), the first step in the synthesis of fat for storage. Hepatic triglycerides are bound to lipoprotein to form very-low-density lipoprotein and then transported and stored in adipocytes. When hepatocytes are energy depleted, triglycerides are broken down to FFAs and glycerol. This process is suppressed by insulin but supported by glucagon or epinephrine. FFAs undergo β -oxidation in the mitochondria, a process that breaks the FFA into acetyl-CoA molecules that can then enter the citric acid cycle. FFAs require activation before transport into the mitochondria. This is accomplished by acylcoenzyme A (acyl-CoA) synthetase, which adds a CoA group to the FFA in an energy-dependent synthetic reaction. These are transported into the mitochondria by a process that utilizes cyclical binding to carnitine, a “carnitine shuttle” (Fig. 13–3). Once inside the mitochondria, FFAs are converted to acetyl-CoA by β -oxidation, involving the sequential removal of two-carbon fragments, each time acting at the second carbon (the β carbon) position of the fatty acid. Each two-carbon molecule removed from the FFA produces one NADH and one FADH_2 , which are oxidized in the electron transport chain, and one mole of acetyl-CoA, which enters the citric acid cycle. This process produces 1.3 times more ATP per molecule of carbon metabolized than does the oxidative metabolism of glucose or other carbohydrates.⁴⁵

Many xenobiotics interrupt fatty acid metabolism at various steps, resulting in accumulation of triglycerides in the liver (Table 13–3; Fig. 13–9). The mechanisms of disruption of fatty acid metabolism are poorly defined.¹⁵ Some xenobiotics, including ethanol, hypoglycin, and nucleoside analogs, inhibit β -oxidation, at least indirectly, through effects on NADH concentrations. Protease inhibitors are associated with a syndrome of peripheral fat wasting, central adiposity, hyperlipidemia, and insulin resistance.

FIGURE 13–9. Steatosis, an accumulation of fat, results when xenobiotics interfere with the oxidation of fatty acids. Other processes that increase intracellular accumulation of fat include impaired lipoprotein synthesis, impaired lipoprotein release, increased mobilization of free fatty acids, increased uptake of circulating lipids, and increased production of triglycerides. β -Oxidation occurs in the mitochondria. The carnitine shuttle is used to transport long-chain fatty acids from the cellular cytosol across the mitochondrial membrane. The enzymes involved are (a) acyl-CoA synthetase, (b) carnitine palmitoyltransferase I, (c) carnitine acylcarnitine translocase, and (d) carnitine palmitoyltransferase II. Acyl-CoA is the intramitochondrial substrate for β -oxidation. Potential mechanisms of inhibition of β -oxidation include induction of carnitine deficiency, inhibition of the transferase or translocase, and increased NADH:NAD⁺ ratio via increased use of NAD⁺ or by inhibition of NADH use. The specific site of action is not defined for many toxins that cause steatosis.

The condition of alcoholic ketoacidosis is related in part to inhibition of gluconeogenesis in the alcoholic patient and in part to an exuberant response to nutritional needs by the fatty acid machinery. Vomiting in the alcoholic patient leads to

decreased intake of carbohydrate, which stimulates a starvation response with increases in serum glucagon, cortisol, growth hormone, and epinephrine concentrations, and decreases in serum insulin. When the need for carbohydrate is not met by gluconeogenesis, lipolysis, which is normally inhibited by insulin, is intensified and fatty acid mobilization progresses. Glucagon stimulates mitochondrial carnitine acyltransferase, and β -oxidation of fatty acids is increased. The increased mitochondrial NADH:NAD⁺ ratio favors the production of β -hydroxybutyrate over acetoacetate, its oxidized form. The administration of fluids, dextrose, and thiamine to the alcoholic patient leads to correction of this process.⁵³

SUMMARY

- Biotransformation is a complex process, involving numerous enzyme systems, that usually detoxifies xenobiotics, however, “metabolic activation” may occur.
- Phase I reactions add functional groups to lipophilic xenobiotics to enhance their reactivity, preparing them for further detoxification by synthetic phase II reactions that enhance hydrophilicity and renal elimination.
- The phase I cytochrome P450 (CYP) enzymes biotransform most xenobiotics; CYP3A4 is the most abundant one, metabolizing 50% to 60% of all pharmaceuticals.
- CYP enzyme activity is quite variable due to genetic polymorphisms, genetic changes that exist in at least 1% of the human population. Enzyme activity also varies because of induction and inhibition.
- The most common method of induction is a nuclear receptor-mediated increase in gene transcription. Inhibition of CYP enzymes is the most common cause of harmful drug–drug interactions, the most common type being competitive, where the substrate and inhibitor both bind the active site of the enzyme.
- Drug disposition is also effected by membrane transporter (MT) proteins that mediate the cellular uptake and efflux of xenobiotics.
- P-glycoprotein is an MT protein that mediates the efflux of xenobiotics from the apical (luminal) membrane of intestinal enterocytes.

¹This table list is not complete and may reflect some variation in author opinions as to whether a xenobiotic is a substrate, inhibitor, or inducer. ²Substrate is sensitive; area under the concentration vs. time curve (AUC) values have been shown to increase 5-fold or more when coadministered with a known CYP1A inhibitor. ³Substrate has a narrow therapeutic range and safety concerns occur when coadministered with an inhibitor. ⁴A strong inhibitor (at least a 5-fold increase in AUC or greater than 80% decrease in clearance). ⁵A strong inducer (at least a 4-fold increase in enzyme activity). ⁶Ritonavir has paradoxical dose and time-dependent inhibitory and induction effects.

NSAID = nonsteroidal antiinflammatory drug; PPI = proton pump inhibitor; SSRI = selective serotonin reuptake inhibitor.

14 NEUROTRANSMITTERS AND NEUROMODULATORS

Steven C. Curry, Ayrn D. O'Connor, Kimberlie A. Graeme, Kirk C. Mills, and Aaron B. Skolnik

This chapter reviews the normal physiology of neurotransmission, the molecular action and biochemistry of several major neurotransmitters and their receptors, and the toxicologic mechanisms by which numerous xenobiotics act at the molecular level. Acetylcholine, norepinephrine, epinephrine, dopamine, serotonin, γ -aminobutyric acid (GABA), γ -hydroxybutyrate (GHB), glycine, glutamate, and adenosine are neurotransmitters and neuromodulators of toxicologic interest discussed herein.

When examining molecular actions of xenobiotics on neurotransmitter systems, it quickly becomes apparent that substances rarely possess single pharmacologic actions. As examples, doxepin, in part, antagonizes voltage-gated sodium channels, histaminic H_1 and H_2 receptors, α -adrenergic receptors, muscarinic acetylcholine receptors, dopamine D_2 receptors, and GABA_A receptors; prevents potassium efflux; and inhibits norepinephrine, serotonin, and adenosine uptake. Similarly, carbamazepine blocks voltage-gated sodium channels; inhibits uptake of norepinephrine, adenosine, and serotonin; antagonizes adenosine and muscarinic receptors; activates GABA_B receptors; and binds to benzodiazepine-binding sites on mitochondria. For obvious reasons, then, this chapter cannot include every action of every xenobiotic on the nervous system. Nor is it meant to be a complete discussion of toxic syndromes produced by various xenobiotics, as these are discussed in specific chapters. Rather, this chapter provides a general and basic understanding of mechanisms of action of various xenobiotics affecting neurotransmitter function and receptors, especially in the central nervous system. With this focus, the clinical effects produced are more easily understood and predicted, and specific treatments can be rationally undertaken. Given the complexity of the nervous system and the numerous actions of a given xenobiotic, it is not always clear which neurotransmitter system is producing an observed effect. Therefore, specific xenobiotics may be found in several sections. An attempt is made to note the major mechanism of action of a xenobiotic, although other actions are noted when possible.

NEURON PHYSIOLOGY AND NEUROTRANSMISSION

Membrane Potentials, Ion Channels, and Nerve Conduction

Membrane-bound sodium-potassium adenosine triphosphatase (ATPase) moves three sodium ions (Na^+) from inside the cell to the interstitial space while pumping two potassium ions (K^+) into the cell. Because the cell membrane is not freely permeable to large, negatively charged intracellular molecules, such as proteins, an equilibrium results in which the inside of the neuron is negative with respect to the outside. This typical neuronal resting membrane potential is -65 mV.

Sodium, calcium (Ca^{2+}), K^+ , and chloride (Cl^-) ions move into and out of neurons through ion channels. When moving through ion channels, which are long polypeptides comprising several subunits that span the plasma membrane multiple times, ions always move passively down electrochemical gradients. Many different ion channels are structurally comparable, sharing similar amino acid sequences.¹⁹ Channels for a specific ion can also vary in structure, depending on the specific subunits that have combined to form the channel. Because of structural similarity of different channels, it is not surprising that many xenobiotics are able to bind to more than one type of ion channel.

More than 40 different ion channels have been described in various nerve terminals,¹²⁸ and it is estimated that a human being contains hundreds of different varieties of ion channels for Na^+ , Cl^- , Ca^{2+} , and K^+ . Most ion channels fall into two general classes: voltage-gated (voltage-dependent) ion channels and ligand-gated ion channels.¹²⁸ Voltage-gated channels open or close in response to changes in membrane potential. Ligand-gated channels open or close when a ligand (eg, neurotransmitter) binds to and changes the conformation of the channel.

A commonly accepted model describes voltage-gated Na^+ channels and some other voltage-gated ion channels in three possible states. Using Na^+ channels as an example, the Na^+ channel is closed at rest and impermeable to Na^+ , preventing Na^+ from moving into the cell. When the channel undergoes activation, the channel opens, allowing Na^+ to move

intracellularly, down its electrochemical gradient. The channel then undergoes a third conformational change by becoming inactivated, preventing further influx of Na^+ . The term recovery describes the conversion of inactive channels back to the resting state, a process that requires repolarization of the cell membrane.

Depolarization of a neuron usually results from an initial inward flux of cations (Na^+ or Ca^{2+}), or prevention of K^+ efflux. The fall in membrane potential (movement toward 0 mV) results in further activation of these voltage-dependent Na^+ channels, allowing yet a greater influx of cations. When the membrane potential falls to threshold, Na^+ channels are activated en masse, and there is a large influx of Na^+ .

Depolarization of a segment of the neurolemma causes the adjacent neuronal membrane to reach threshold, resulting in the propagation of an action potential down the neuron. Sodium channel activation is quickly followed by inactivation, ending depolarization. Over the short-term, repolarization of the neuron subsequently occurs mainly from efflux of K^+ and some influx of Cl^- .

Neurotransmitter Release

Neurotransmitters are chemicals that are released from nerve endings into the synapse, where they produce effects by binding to receptors on postsynaptic or presynaptic cell membranes. The receptors may be on other neurons or effector organs such as smooth muscle. Concentrations of neurotransmitters in cytoplasm are usually low because of rapid enzymatic degradation and diffusion out of the nerve ending. To provide a source of neurotransmitters that is protected from degradation and that can rapidly be released, neurotransmitters are concentrated and stored within vesicles in the nerve terminal. As a wave of depolarization from Na^+ influx reaches the nerve ending, the membrane depolarization causes voltage-gated Ca^{2+} channels to open, allowing Ca^{2+} to move rapidly into the cell. This influx of Ca^{2+} triggers exocytosis of vesicle contents into the synapse via the *snare complex*. The voltage-gated Ca^{2+} channels responsible for inward Ca^{2+} currents that trigger neurotransmitter release are members of the Ca_v2 subfamily (N, P/Q, and R subtypes).^{134,164}

Ziconotide, a derivative of a conotoxin that is used for analgesia, blocks N-type Ca^{2+} channels on nociceptive neurons in the dorsal root to prevent neurotransmitter release. Cardiovascular calcium channel blockers used in clinical practice do not block these subtypes of voltage-dependent Ca^{2+} channels, but block the L-subtype. However, L-subtype Ca^{2+} channels reside elsewhere on neurons, thus explaining the ability of traditional Ca^{2+} channel blockers to affect some neurologic functions.

Vesicle Transport of Neurotransmitters

The pH inside neurotransmitter vesicles is about 5.5, which is lower than that in the cytoplasm. A vacuolar ATPase in the vesicular membrane is responsible for movement of protons into the vesicular lumen at the expense of ATP hydrolysis. Vesicular uptake pumps (transporters) that move neurotransmitters or their precursors from the cytoplasm into the vesicle lumen, in turn, are powered by the electrochemical H^+ gradient. That is, the movement of an H^+ out of the vesicle into the cytoplasm is coupled to the movement of a neurotransmitter from the cytoplasm into the vesicle.

Various vesicular transporters for neurotransmitters have been sequenced to date. VGAT transports GABA and glycine. VMAT2 transports all three monoamines, dopamine, norepinephrine, and serotonin (VMAT1 transports monoamines into non-neuronal vesicles). VACHT is responsible for acetylcholine (ACh) transport, and 3 VGluTs (VGluT1-3) move glutamate into vesicles.

Neurotransmitters are confined within the vesicle, to a great extent, by ion trapping, as they are more ionized and less able to diffuse back out of the vesicle at the lower pH. Anything that causes a decrease in the pH gradient across the vesicle membrane results in the movement of neurotransmitters into the cytoplasm.¹⁹⁷ For example, amphetamines move into vesicles, where they buffer protons, causing the movement of monoamine neurotransmitters out of vesicles, and raising cytoplasmic concentrations of neurotransmitters, and ultimately raising the synaptic monoamine concentration.^{197,198}

Neurotransmitter Reuptake

Although acetylcholine is inactivated in the synapse by enzymatic degradation, other neurotransmitters have their synaptic effects terminated by active uptake into neurons or glial cells. These plasma membrane neurotransmitter transporters are distinct from those transporters responsible for movement of neurotransmitters into vesicles. Cell membrane transporters for different neurotransmitters are Na^+ -dependent transport proteins, during which the uptake of neurotransmitters is accompanied by the movement of Na^+ across the synaptic membrane.² These uptake transporters are commonly known as either uptake or reuptake pumps; the term “reuptake” will be used in this chapter for purposes of consistency.

Neurotransmitter reuptake transporters are subdivided into two main families.² One family (SLC6) includes structurally similar uptake pumps for GABA, glycine, norepinephrine, dopamine, and serotonin. They generally comprise 600 to 700 amino acids and form loops spanning the plasma membrane 12 times. Four GABA reuptake transporters (GAT-1 through

GAT-4) transport GABA into neurons and glial cells. DAT, SERT, and NET are responsible for reuptake of dopamine, serotonin, and norepinephrine, respectively. GLYT-1 and GLYT-2 are responsible for glycine uptake into neurons or astrocytes.

The second family (SLC1) comprises five glutamate reuptake transporters (excitatory amino acid transporters {EAATs}), which appear to traverse the plasma membrane 10 times and move glutamate from the synapse into glial cells and neurons.

Several properties make transporter proteins of particular toxicologic significance. First, they are capable of moving neurotransmitters in either direction; when cytoplasmic neurotransmitter concentrations are significantly elevated, neurotransmitters can be transported back into the synapse. Second, these transporters are not always completely specific. For instance, the uptake transporter for norepinephrine can move dopamine and other bioactive amines into the neuron. Third, a xenobiotic that acts at the level of the membrane transporter may affect functions of several different neurotransmitters, depending on its specificity for a particular transporter. As an example, fluoxetine is fairly specific at inhibiting reuptake of serotonin, whereas cocaine inhibits the reuptake of serotonin, norepinephrine, and dopamine.

Neurotransmitter Receptors

Channel Receptors. The first general class of neurotransmitter receptors comprises ligand-gated ion channels (LGICs; channel receptors; ionotropic receptors), in which the receptor for the neurotransmitter is part of an ion channel. These channels comprise multiple subunits that combine in various combinations to create channels that vary in response to a given neurotransmitter or other agonist/antagonist. LGICs for neurotransmitters discussed in this chapter are divided into two main groups, based on structure of subunits and assemblies. Most neurotransmitter LGICs are pentameric and display four transmembrane helices. LGICs for glutamate, however, are tetrameric and comprise three transmembrane helices.¹²⁰

By binding to its LGIC receptor, the neurotransmitter allosterically changes the configuration of the ion channel so that ions traverse the channel in greater quantities per unit time. As an example, the acetylcholine nicotinic receptor at the neuromuscular junction is a ligand-gated Na⁺ channel. When acetylcholine binds to the nicotinic receptor, the channel’s configuration changes, allowing Na⁺ to move into the cell and trigger an action potential. The action potential then propagates down muscle via voltage-gated Na⁺ channels. Table 14–1 lists other examples of channel receptors.

TABLE 14–1. Types of Neurotransmitter and Neuromodulator Receptors	
<i>Ion Channel</i>	<i>G Protein–Coupled Receptor</i>
ACh nicotinic	ACh muscarinic
GABA _A	GABA _B
Glycine (inhibitory)	Dopamine
Glutamate AMPA	Norepinephrine
Glutamate NMDA	5-HT _{1,2,4–7}
Glutamate kainate	Adenosine
5-HT ₃	Glutamate metabotropic

ACh = acetylcholine; AMPA = amino-3-hydroxy-5-methyl-4-isoxazole propionate; GABA = γ-aminobutyric acid; 5-HT = 5-hydroxytryptamine (serotonin); NMDA = N-methyl-D-aspartate.

G Protein–Coupled Receptors. The second general class of neurotransmitter receptors are linked to G proteins, which are part of a superfamily of proteins with guanosine triphosphatase (GTPase) activity responsible for signal transduction across plasma membranes.¹⁸⁷ G proteins comprise three polypeptide subunits: α, β, and γ chains. These chains span the plasma membrane several times, and they associate with a separately transcribed neurotransmitter receptor that spans the cell membrane seven times, with an external binding site for neurotransmitters. Some receptors (eg, GABA_B receptor) coupled to G proteins are obligatory heterodimers comprising two separate proteins, both of which must be present for activity.

Both the α subunit and the β-γ subunits of a G protein may account for activity resulting from a neurotransmitter binding to its receptor. The α chain normally binds guanosine diphosphate (GDP) in the cytoplasm and is inactive. When a neurotransmitter binds to its receptor on the outside of the cell membrane, GDP dissociates from the α chain and guanosine triphosphate (GTP) binds in its place, activating the α subunit. The activated α subunit then dissociates from receptor and from the β and γ chains. Both the activated α subunit and β-γ subunits modulate effectors in the plasma membrane.¹⁸⁷ The effector influenced by α or β-γ subunits may be an enzyme that the subunits stimulate or inhibit (eg, adenylate cyclase) or an ion channel that is opened or closed directly or through other chemical reactions (eg, channel phosphorylation).³² Intrinsic

GTPase activity in the α chain eventually converts the GTP to GDP, inactivating the α subunit and allowing it to reassociate with the β - γ chains and the neurotransmitter receptor, terminating the consequences of neurotransmitter binding.¹⁸⁷

G proteins are mainly categorized by the type of α chain they contain. The three main families of G proteins coupled to neurotransmitter receptors are G_s (containing the α_s subunit), $G_{i/o}$ (containing α_i or α_o), and G_q (or $G_{q/11}$ containing α_q). G_s stimulates membrane-bound adenylate cyclase; activation of a neurotransmitter receptor coupled to G_s causes a rise in intracellular 3',5'-cyclic adenosine monophosphate (cAMP) concentration. Neurotransmitter receptors activating G_i may inhibit adenylate cyclase or modulate K^+ and Ca^{2+} channels. Receptors coupled to G_q act through membrane-bound phospholipase C to increase intracellular calcium concentrations. See Table 14–1 for a list of the neurotransmitter receptors coupled to G proteins. A given neurotransmitter can activate different classes of receptors (eg, ion-channel and G protein) or different types of receptors in the same class. For example, $GABA_A$ receptors are Cl^- channels, whereas $GABA_B$ receptors are coupled to G proteins. Dopamine D_1 -like receptors (D_1 and D_5) are linked to G_s , whereas D_2 -like receptors (D_2 , D_3 , and D_4) are linked to G_i or G_o .

Importantly, a single G protein-coupled receptor may activate more than one type of G protein in the same cell, depending on various circumstances, including duration of receptor activation. Evidence continues to accumulate indicating that G protein-coupled receptors for the same or different neurotransmitters can form both heterodimers and oligomers, resulting in yet more variation in response to neurotransmitter binding. Examples may include combinations of various dopamine receptors, combinations of dopamine and 5-HT receptors, and combinations of dopamine and glutamate receptors.^{135,137,172}

Receptor downregulation occurs at various levels. For example, prolonged receptor activation results in receptor phosphorylation by G protein kinases (GPKs), causing receptor binding to a member of the arrestin family of proteins. This, in turn, prevents further activation of the G protein by the receptor, and eventually triggers receptor endocytosis.^{3,104,183}

Neuronal Excitation and Inhibition

Excitatory neurotransmitters usually act postsynaptically by causing Na^+ or Ca^{2+} influx, or by preventing K^+ efflux, triggering depolarization and an action potential (Fig. 14–1). These effects may be mediated by channel or G protein-coupled receptors.

FIGURE 14–1. Common mechanisms of postsynaptic excitation and inhibition. (A) An excitatory neurotransmitter (ENT)

binds to receptors linked to G proteins to prevent K^+ efflux [1] or to allow Na^+ influx [2], producing membrane depolarization. An ENT may bind to and activate a cation channel [3] to allow Na^+ and/or Ca^{2+} influx with resultant membrane depolarization. **(B)** An inhibitory neurotransmitter hyperpolarizes the membrane (makes membrane potential more negative) by binding to receptors linked to G proteins to enhance K^+ efflux [4], or to Cl^- channels to allow Cl^- influx [5]. Some Cl^- channels are regulated by G proteins as well. G = G protein.

Postsynaptic inhibition can be mediated by channel receptors or by receptors coupled to G proteins (Fig. 14–1). Inhibition is usually accomplished by neuronal influx of Cl^- or efflux of K^+ to hyperpolarize the neuron and move membrane potential farther away from threshold, making it more difficult for a given stimulus to depolarize the membrane to threshold voltage.

Presynaptic inhibition, the prevention of neurotransmitter release, is usually mediated by receptors coupled to G proteins. When a neurotransmitter released from a neuron binds to a receptor on that same neuron to limit further neurotransmitter release, the receptor is termed an autoreceptor.^{176,139} Autoreceptors reside on dendrites, cell bodies, axons, and presynaptic terminals. Autoreceptors on dendrites and cell bodies (somatodendritic autoreceptors) usually inhibit further neurotransmitter release by increasing K^+ efflux, thereby hyperpolarizing the neuron away from threshold (Fig. 14–2). However, activation of autoreceptors found on presynaptic terminals (terminal autoreceptors) usually limits increases in intracellular Ca^{2+} concentration by limiting Ca^{2+} influx or preventing Ca^{2+} release from intracellular stores, impairing exocytosis of neurotransmitter vesicles (Fig. 14–2). Types of neurotransmitter receptors that serve as autoreceptors also usually reside postsynaptically, where they may mediate different physiologic effects.

FIGURE 14–2. Common mechanisms of presynaptic inhibition (the inhibition of neurotransmitter {NT} release). A neuron releases NT (green dots), which returns to activate receptors on the cell body or dendrites (somatodendritic autoreceptors), or on the axonal terminal (terminal autoreceptors). Such activation limits further release of NT by completing a negative feedback loop. At somatodendritic autoreceptors, NT binding produces activation of G proteins, which promote either K^+ efflux or Cl^- influx; both processes hyperpolarize the neuron away from threshold. At terminal autoreceptors, NT binding activates G proteins, which, through various mechanisms, lower intracellular Ca^{2+} concentrations to prevent exocytosis of NT vesicles, despite depolarization. Presynaptic inhibitory receptors for other types of NTs (heteroreceptors) are also shown. Excitatory axonal terminal autoreceptors and heteroreceptors that serve to enhance neurotransmitter release are not illustrated. G = G protein.

Inhibition of neurotransmitter release from nerve terminals is not limited to actions by autoreceptors. Presynaptic terminal inhibitory receptors for various neurotransmitters may be found on a single neuron (heteroreceptors). For example, stimulation of presynaptic α_2 receptors found on postganglionic parasympathetic nerve terminals prevents acetylcholine release.

Finally, stimulation of receptors on presynaptic nerve endings may enhance, rather than inhibit, neurotransmitter release. Such receptors also are usually coupled to G proteins. For example, stimulation of β_2 receptors on adrenergic nerve terminals enhances norepinephrine release.

ACETYLCHOLINE

Acetylcholine (ACh) is a neurotransmitter of the central and peripheral nervous system. Centrally, it is found in both brain and spinal cord; cholinergic fibers project diffusely to the cerebral cortex. Peripherally, ACh serves as a neurotransmitter in autonomic and somatic motor fibers (Fig. 14–3).

FIGURE 14–3. Diagram of the cholinergic nervous system, including adrenergic involvement in the autonomic nervous system. ACh binds to various nicotinic receptors (N) in CNS, in sympathetic and parasympathetic ganglia, and the adrenal glands. All nicotinic receptors shown are neuronal nicotinic receptors (nnAChRs) except for those at skeletal muscle, which are neuromuscular junction nicotinic receptors (NMJ nAChRs). ACh also binds to various subtypes of muscarinic (M) receptors in the CNS and on effector organs innervated by postsynaptic parasympathetic neurons and to most sweat glands. NE and/or EPI released in response to ACh stimulation of nnAChRs activates α- and β-adrenergic receptors. ACh = acetylcholine; CNS = central nervous system; EPI = epinephrine; NE = norepinephrine.

Synthesis, Release, and Inactivation

Acetylcholine is synthesized from acetyl coenzyme A and choline by the enzyme choline acetyltransferase. Acetylcholine moves into synaptic vesicles via the vesicular membrane transporter, VACHT, where it is stored before release into the synapse by Ca²⁺-dependent exocytosis. ACh undergoes enzymatic degradation in the synapse to choline and acetic acid by acetylcholinesterase. A Na⁺-dependent transporter in the neuronal membrane (ChT) then pumps choline back into the cytoplasm to be used again as a substrate for ACh synthesis (Fig. 14–4). Pseudocholinesterase (also known as plasma cholinesterase or butyryl cholinesterase) is made in the liver and plays no role in the degradation of synaptic ACh. However, it does metabolize some xenobiotics, including cocaine and succinylcholine.

FIGURE 14–4. Cholinergic nerve ending. Activation of postsynaptic muscarinic receptors (mAChR) hyperpolarizes the postsynaptic membrane through G protein-mediated enhancement of K⁺ efflux. Several subtypes of muscarinic receptors coupled to various G proteins exist—a muscarinic receptor coupled to a G protein that opens K⁺ channels is shown only as an example [2]. Postsynaptic nicotinic receptor (nAChR) activation causes Na⁺ influx and membrane depolarization [3]. Ca²⁺ influx appears to be the main cation involved with some neuronal nicotinic receptors. Presynaptic muscarinic and α₂-adrenergic receptor activation prevents ACh release through lowering of intracellular Ca²⁺ concentrations. The xenobiotics listed in Table 14–2 may act to enhance or prevent release of ACh [1]; activate or antagonize postsynaptic muscarinic (M) receptors [2]; activate or antagonize nicotinic (N) receptors [3]; inhibit acetylcholinesterase [4]; prevent ACh release by stimulating presynaptic muscarinic autoreceptors [5] or α₂-adrenergic heteroreceptors [6]; or enhance ACh release by antagonizing presynaptic autoreceptors [5] or by antagonizing presynaptic α₂-adrenergic heteroreceptors [6] (on parasympathetic postganglionic terminals). ACh = acetylcholine; AChE = acetylcholinesterase; G = G protein; VACHT = vesicular transporter for ACh. Norepinephrine is shown as light blue dots.

TABLE 14–2. Examples of Xenobiotics Affecting Cholinergic Neurotransmission

Cholinomimetics	Cholinolytics
Cause ACh release	Direct nicotinic antagonists
α_2 -Adrenergic receptor antagonists ^a	α -Bungarotoxin ^c
Aminopyridines	Nondepolarizing neuromuscular blockers
Black widow spider venom	Trimethaphan
Carbachol	Indirect neuronal nicotinic antagonists
Guanidine	Physostigmine
Anticholinesterases	Tacrine
Donepezil	Galantamine
Edrophonium	Direct muscarinic antagonists
<i>N</i> -methylcarbamate insecticides	Antihistamines
Organic phosphorus insecticides	Atropine
Physostigmine	Benztropine
Rivastigmine	Clozapine
Direct nicotinic agonists	Cyclic antidepressants
Carbachol	Cyclobenzaprine
Coniine	Disopyramide
Cytisine	Orphenadrine
Nicotine	Phenothiazines
Succinylcholine ^b	Procainamide
Varenicline	Scopolamine
Indirect neuronal nicotinic agonists	Trihexyphenidyl
Chlorpromazine	Inhibit ACh release
Ethanol	α_1 -Adrenergic receptor agonists ^d
Ketamine	Botulinum toxins
Local anesthetics	Crotalinae venoms
Phencyclidine	Elapidae β -neurotoxins
Volatile anesthetics	Hypermagnesemia
Direct muscarinic agonists	
Arecoline	
Bethanechol	
Carbachol	
Cevimeline	
Methacholine	
Muscarine	
Pilocarpine	

^aAntagonism of α_2 -adrenoceptors enhances ACh release from parasympathetic nerve endings. ^bDepolarizing neuromuscular blockers. ^c α -Bungarotoxin exemplifies many elapid α -neurotoxins that produce paralysis and death from respiratory failure. ^dStimulation of presynaptic α_1 -adrenergic receptors on parasympathetic nerve endings prevents ACh release.

ACh = acetylcholine.

Acetylcholine Receptors

Nicotinic Receptors. After release from cholinergic nerve endings, ACh activates two main types of receptors: nicotinic and muscarinic.¹⁰⁵ Nicotinic receptors (nAChRs) reside in the CNS (mainly in spinal cord), on postganglionic autonomic neurons (both sympathetic and parasympathetic), in the adrenal medulla, and at skeletal neuromuscular junctions, where they mediate muscle contraction (Fig. 14-3).

Nicotinic receptors at neuromuscular junctions (NMJ nAChRs) are part of a Na^+ channel made from five protein subunits. Stimulation of these receptors by ACh results mainly in Na^+ influx, depolarization of the endplate, and triggering of an action potential that is propagated down the muscle by voltage-gated Na^+ channels.

Nicotinic receptors on central or peripheral neurons or in the adrenal gland are termed neuronal nAChRs. Neuronal nAChRs are also ion channels, although in some cases Ca^{2+} influx through the receptor may be more important than Na^+ influx. Neuronal nAChRs also comprise five subunits.

Muscarinic Receptors. Muscarinic receptors reside in the CNS (mainly in the brain), on end organs innervated by

postganglionic parasympathetic nerve endings, and at most postganglionic sympathetically innervated sweat glands (Fig. 14–3). Five subtypes of muscarinic receptors, M_{1-5} , are recognized and linked to several G proteins. For example, in the heart, ACh released from the vagus nerve binds to M_2 receptors linked to G_i . G_i opens K^+ channels, allowing efflux of K^+ down its concentration gradient, which makes the inside of the cell more negative and more difficult to depolarize, slowing the heart rate. Different subtypes of muscarinic receptors also act as autoreceptors in various locations, M_1 being the most common.

Xenobiotics

Table 14–2 provides examples of xenobiotics that affect cholinergic neurotransmission.

Modulators of Acetylcholine Release. Figure 14–4 illustrates sites of actions of numerous xenobiotics that influence the cholinergic nervous system. Botulinum toxins, some neurotoxins from pit vipers, and elapid β -neurotoxins prevent release of ACh from peripheral nerve endings.⁷² This results in ptosis, other cranial nerve findings, weakness, and respiratory failure. Hypermagnesemia also inhibits ACh release, probably by inhibiting Ca^{2+} influx into the nerve endings.¹⁰⁵

Guanidine, aminopyridines, and black widow spider venom enhance the release of ACh from nerve endings. Aminopyridines, in part, block voltage-gated K^+ channels to prevent K^+ efflux; the resultant action potential widening (delayed repolarization) causes prolongation of Ca^{2+} channel activation, enhancing influx of Ca^{2+} , which promotes neurotransmitter release. Aminopyridines are used therapeutically in Lambert–Eaton syndrome, myasthenia gravis, multiple sclerosis, and experimentally in calcium channel blocker overdose.

Black widow spider venom causes ACh release by opening neuronal Ca^{2+} channels with resultant muscle cramping and diaphoresis.⁸

Nicotinic Receptor Agonists and Antagonists. Xenobiotics that bind to and activate nicotinic receptors may stimulate postganglionic sympathetic and parasympathetic neurons, skeletal muscle end-plates, the adrenal medulla, and neurons within the CNS (Fig. 14–3). Prolonged depolarization at the receptor eventually causes diminution of responses to receptor occupancy.¹⁵³ For example, poisoning by nicotine, both a neuronal and NMJ nAChR agonist, may produce hypertension, tachycardia, vomiting, diarrhea, muscle fasciculations, and convulsions, followed by hypotension, bradydysrhythmias, paralysis, and coma. Succinylcholine is a neuromuscular blocker that initially stimulates and then blocks muscular activity through prolonged depolarization of NMJ nAChRs.

Xenobiotics that block NMJ nAChRs without stimulation at skeletal neuromuscular junctions produce weakness and paralysis. Examples include tubocurarine and atracurium. α -Neurotoxins from elapids (eg, α -bungarotoxin) directly antagonize NMJ nAChRs, producing ptosis, weakness, and respiratory failure from paralysis.²¹⁴

Peripheral neuronal nAChR blockade produces autonomic ganglionic blockade. Trimethaphan was used as a pharmacologic ganglionic blocker; however, it is not entirely specific for neuronal nAChRs. Occasionally, trimethaphan caused weakness and paralysis from NMJ nAChR blockade.

The function of neuronal nAChRs can be modulated by a variety of xenobiotics that do not bind to the ACh binding site, but bind instead to a number of distinct allosteric sites. For example, aside from their ability to inhibit acetylcholinesterase, physostigmine, tacrine, and galantamine bind to a noncompetitive allosteric activator site on neuronal nAChRs to enhance channel opening and ion conductance. Furthermore, a diverse range of xenobiotics, including chlorpromazine, phencyclidine, ketamine, local anesthetics, and ethanol bind to a noncompetitive negative allosteric site(s) on nAChRs to inhibit inward ion fluxes without directly affecting ACh binding. Steroids can desensitize neuronal nAChRs by binding to yet an additional allosteric site.¹⁵⁵

Muscarinic Receptor Agonists and Antagonists. Peripheral muscarinic agonists produce bradycardia, miosis, salivation, lacrimation, vomiting, diarrhea, bronchospasm, bronchorrhea, and micturition. Central muscarinic agonists produce sedation, extrapyramidal dystonias, rigidity, coma, and convulsions. The anticholinergic toxic syndrome results from blockade of muscarinic receptors and is more appropriately referred to as an antimuscarinic toxic syndrome.¹⁷⁹ CNS muscarinic blockade produces confusion, agitation, myoclonus, tremor, picking movements, abnormal speech, hallucinations, and coma. Peripheral antimuscarinic effects include mydriasis, anhidrosis, tachycardia, and urinary retention. Muscarinic antagonists number in the hundreds (Table 14–2 for common examples).

Acetylcholinesterase Inhibition. Xenobiotics inhibiting acetylcholinesterase (ie, anticholinesterase) raise ACh concentrations at both nicotinic and muscarinic receptors, producing a variety of CNS, sympathetic, parasympathetic, and skeletal muscle signs and symptoms.³⁴ Anticholinesterases include organic phosphorus compounds and N-methylcarbamates. Organic phosphorus compounds are usually encountered as insecticides, although topical medicinal organic phosphorus compounds are used for the treatment of glaucoma and lice. N-methylcarbamates are found as insecticides and pharmaceuticals. Medicinal N-methylcarbamates include physostigmine, pyridostigmine, rivastigmine, and neostigmine. Edrophonium, galantamine, tacrine, donepezil, and metrifonate are non-carbamate, reversible anticholinesterases.

α_2 -Adrenergic Receptor Agonists and Antagonists. Agonists and antagonists of α_2 -adrenergic receptors are discussed in detail below. Briefly, stimulation of presynaptic α_2 -adrenergic receptors on postganglionic parasympathetic nerve endings decreases ACh release. Conversely, presynaptic α_2 antagonism increases ACh release (Fig. 14–4).

NOREPINEPHRINE AND EPINEPHRINE

Norepinephrine (NE), epinephrine (EPI), dopamine (DA), and serotonin (5-hydroxytryptamine {5-HT}) are similar in many respects. Neurotransmitter synthesis, vesicle transport and storage, uptake, and degradation share many enzymes and structurally similar transport proteins. Cocaine, reserpine, amphetamines, and monoamine oxidase inhibitors (MAOIs) affect all four types of neurons. In addition, these xenobiotics produce several different effects in the same system. For example, in the noradrenergic neuron, amphetamines work mainly by causing the release of cytoplasmic NE, but they also inhibit NE reuptake, and their metabolites inhibit monoamine oxidase. Actions of xenobiotics that affect all bioactive amine neurotransmitters are described in the most detail for noradrenergic neurons. For the sake of brevity, similar mechanisms of action are simply noted in discussions of dopaminergic and serotonergic neurotransmission.

Norepinephrine is released from postganglionic sympathetic terminals (Fig. 14–3). The adrenal gland, acting as a modified sympathetic ganglion, releases EPI and lesser amounts of NE in response to stimulation of neuronal nAChRs. Epinephrine-containing neurons also reside in the brainstem.

The locus ceruleus is the main noradrenergic nucleus and resides in the floor of the fourth ventricle on each side of the pons. Axons radiate from this nucleus out to all layers of the cerebral cortex, to the cerebellum, and to other structures. Norepinephrine demonstrates both excitatory and inhibitory actions in the CNS. Norepinephrine released from locus ceruleus projections in the hippocampus increases cortical neuron activity through β -adrenergic receptor activation and G protein-mediated inhibition of K^+ efflux. Norepinephrine released in outer cortical areas produces inhibitory effects mediated by α_2 -adrenergic receptor agonism. Consistent with this, NE demonstrates anticonvulsant actions in animals. The anticonvulsant action of carbamazepine may be partly a result of inhibition of NE uptake.⁵⁴ Despite antagonistic actions on different cortical neurons, electrical stimulation of the locus ceruleus produces widespread cortical activation and excitation. This overall effect probably explains a great deal of the hyperattentiveness and lack of fatigue that accompanies use of xenobiotics that mimic or increase noradrenergic activity in the brain. Neuronal firing in the locus ceruleus increases during waking and dramatically falls during sleep.

Synthesis, Release, and Reuptake

Figure 14–5 is a representation of a noradrenergic neuron. Tyrosine hydroxylase is the rate-limiting enzyme in NE synthesis and is sensitive to negative feedback by NE. This enzyme requires Fe^{2+} as a cofactor and exists as a homotetramer that is upregulated by chronic exposure to caffeine and nicotine. Under normal dietary conditions tyrosine hydroxylase is completely saturated by tyrosine, and increasing dietary tyrosine does not appreciably increase dopa synthesis. Dopa undergoes decarboxylation by L-amino acid decarboxylase (dopa decarboxylase) to DA. Dopa decarboxylase is not specific for dopa. For example, it also catalyzes the formation of serotonin from 5-HT.

FIGURE 14–5. Noradrenergic nerve ending. The postsynaptic membrane may represent an end organ or another neuron in the CNS. Brief examples of effects resulting from postsynaptic receptor activation are shown. Xenobiotics in [Tables 14–4 and 14–5](#) produce effects by inhibiting transport of dopamine (DA) or norepinephrine (NE) into vesicles through VMAT2 [1]; causing movement of NE and DA from vesicles into the cytoplasm [2]; activating or antagonizing postsynaptic α - and β -adrenergic receptors [3–5]; modulating NE release by activating or antagonizing presynaptic α_2 -autoreceptors [6], dopamine₂ (D_2) heteroreceptors [10], or β_2 -autoreceptors [11]; blocking reuptake of NE (NET inhibition) [7]; causing reverse transport of NE from the cytoplasm into the synapse via NET by raising cytoplasmic NE concentrations [8]; inhibiting monoamine oxidase (MAO) to prevent NE degradation [9]; or inhibiting COMT to prevent NE degradation [12]. AADC = aromatic L-amino acid decarboxylase; β -hydroxylase = dopamine- β -hydroxylase; COMT = catechol-O-methyltransferase; CNS = central nervous system; DOPGAL = 3,4-dihydroxyphenylglycoaldehyde; G = G protein; NET = membrane NE reuptake transporter; NME = normetanephrine; VMAT2 = vesicle uptake transporter for NE.

About one-half of cytoplasmic DA is actively pumped into vesicles by VMAT2. The remaining DA is quickly deaminated.

In the vesicle, DA is converted to NE by dopamine- β -hydroxylase. Vesicles isolated from peripheral nerve endings contain DA, NE, dopamine- β -hydroxylase, and ATP, and all of these substances are released into the synapse during Ca^{2+} -dependent exocytosis triggered by neuronal firing. In neurons containing EPI as a neurotransmitter, NE is released from vesicles into the cytoplasm, where it is converted to EPI by phenylethanolamine-N-methyl-transferase. Epinephrine is then transported back into vesicles before synaptic release.¹⁰⁵

Norepinephrine is removed from the synapse, mainly by reuptake into the presynaptic neuron by the NE transporter (NET). Although this transporter has great affinity for NE, it also transports other amines, including DA, tyramine, MAOIs, and amphetamines. Once pumped back into the cytoplasm, NE can either be transported back into vesicles for further storage and release, or can be quickly degraded by monoamine oxidase (MAO), an enzyme expressed on the outer mitochondrial membrane.

MAO is present in all human tissues except red blood cells. It exists as two isozymes, MAO-A and MAO-B,¹²⁷ each

with partially overlapping substrate affinities (Table 14–3). Neuronal MAO, bound to the outer mitochondrial membrane, oxidatively deaminates cytoplasmic amines, including neurotransmitters, to attenuate elevated cytoplasmic concentrations of bioactive amines. Hepatic and intestinal MAO prevents large quantities of dietary bioactive amines from entering the circulation and producing systemic effects.

Catechol-O-methyltransferase (COMT) is an intracellular enzyme widely distributed throughout the body, including the central nervous system, which is responsible for metabolism of DA, L-dopa, NE, and EPI. In extraneuronal tissue, COMT metabolizes catecholamines, including those that have entered the systemic circulation.

Adrenergic Receptors

The two main types of adrenergic receptors are α -adrenergic receptors and β -adrenergic receptors. All adrenergic receptors are coupled to G proteins.

β -Adrenergic Receptors. β -Adrenergic receptors are divided into three major subtypes (β_1 , β_2 , and β_3), depending on their affinity for various agonists and antagonists.¹⁸¹ β_1 -adrenergic receptors and β_2 -adrenergic receptors are linked to G_s , and their stimulation raises cAMP concentration and/or activates protein kinase A which, in turn, produces several effects, including regulation of ion channels. At least some β_3 -adrenergic receptors may be coupled to $G_{i/o}$ proteins. Up-regulation of β_3 receptors responsible for a negative inotropic effect in diseased myocardium may protect against adverse effects of chronic excessive catecholamine stimulation. β_3 receptor activation by nebivolol may also be responsible for nitric oxide production in some vascular beds.⁶³

The β -adrenergic receptors are polymorphic, with genetic variation in humans.^{26,86} Polymorphism influences response to medications, regulation of receptors, and clinical course of disease.^{26,87,109} In general, peripheral β_1 -adrenergic receptors are found mainly in the heart and in the juxtaglomerular apparatus. β_2 -adrenergic receptors also reside in the heart as well as other organs where their activation mediates additional adrenergic effects such as bronchodilation and vasodilation.⁸⁷ Presynaptic β_2 -adrenergic receptor activation causes release of NE from nerve endings (positive feedback). β_3 -adrenergic receptors reside mainly in fat, but they also reside in skeletal muscle, gallbladder, and colon where they regulate metabolic processes. β_3 -adrenergic receptors' polymorphism may contribute to clinical expressions of non-insulin-dependent diabetes and obesity.^{26,196,216}

α -Adrenergic Receptors. α -Adrenergic receptors are linked to G proteins that inhibit adenylate cyclase to lower cAMP concentrations, affect ion channels, increase intracellular Ca^{2+} through inositol triphosphate and diacylglycerol production, or produce other actions. These receptors are divided into two main types, α_1 and α_2 , and at least six subtypes— α_{1A} , α_{1B} ,

α_{1D} , α_{2A} , α_{2B} , and α_{2C} .^{47,80,181} Most α_1 -adrenergic receptors are coupled to G_q , whereas most α_2 -adrenergic receptors are coupled to $G_{i/o}$.

In peripheral tissue, α_1 -adrenergic receptors reside on the postsynaptic membrane in continuity with the synaptic cleft. Stimulation of these receptors on blood vessels commonly results in vasoconstriction.

α_2 -Adrenergic receptors reside on both sides of the synapse. Presynaptic α_2 -adrenergic receptor activation mediates negative feedback, limiting further release of NE (Fig. 14–5). Postganglionic parasympathetic neurons also contain presynaptic α_2 -adrenergic receptors that, when stimulated, prevent release of ACh (Fig. 14–4).

Postsynaptic α_2 -adrenergic receptors on vasculature also can mediate vasoconstriction. Initially, it was suggested that postsynaptic α_2 -adrenergic receptors resided mainly outside of the synapse and mediated vasoconstrictive responses to circulating α -adrenergic agonists such as NE, whereas postsynaptic α_1 -adrenergic receptors responded to NE released from nerve endings. However, it has been demonstrated that in at least some tissues (eg, saphenous vein), NE released following nerve stimulation produces vasoconstriction through action at α_2 -adrenergic receptors, making the previous differentiation not as distinct.^{47,95} Because both α_1 -adrenergic receptors and α_2 -adrenergic receptors on non-cerebral vasculature mediate vasoconstriction, a patient with hypertension from high concentrations of circulating catecholamines (eg, pheochromocytoma or clonidine withdrawal) or from extravasation of NE from an intravenous line commonly requires both α_1 -adrenergic receptor and peripheral α_2 -adrenergic receptor blockade to vasodilate adequately (eg, phentolamine).

Stimulation of postsynaptic α_2 -adrenergic receptors in the brainstem inhibits sympathetic output and produces sedation. α_{2A} -Adrenergic heteroreceptor activation on non-noradrenergic cells is important in explaining sedation, antinociception, hypothermia, effects on cognition, and centrally mediated bradycardia and hypotension in response to administration of α_2 agonists (Fig. 14–6).⁶⁷ Dexmedetomidine, an imidazole and potent α_{2A} -adrenergic receptor agonist, is used for sedation in intensive care patients, although hypotension and bradycardia occur as expected side effects.¹⁸

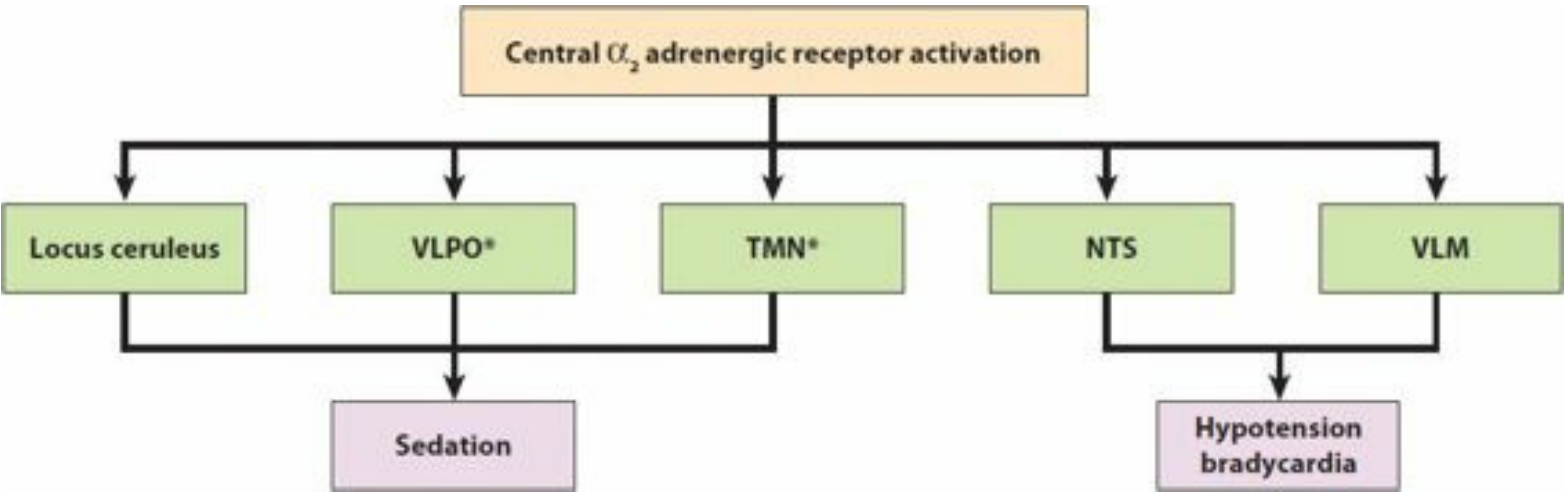

FIGURE 14–6. Central action of agents that activate α_2 -adrenergic receptors. Activation of α_2 -adrenergic receptors on noradrenergic neurons in the locus ceruleus produces sedation. Activation of receptors in the nucleus tractus solitarius (NTS) and ventrolateral medulla (VLM) contributes to hypotension and bradycardia. *In animal models, α_2 -receptor activation of GABAergic neurons in the ventrolateral preoptic nucleus (VLPO) and of histaminergic neurons in the tuberomamillary nucleus (TMN) also contributes to sedation, and may do so in humans.

Xenobiotics

Xenobiotics producing pharmacologic effects that result in or mimic increased activity of the adrenergic nervous system are sympathomimetics (Table 14–4). Those with the opposite effect are sympatholytics (Table 14–5).

^aPartial β -adrenergic receptor agonist. ^bXenobiotics in these categories vary in their relative selectivity for α_2 -adrenoceptors or imidazoline-binding sites. ^cMetabolized to α -methylnorepinephrine, which activates α_2 -adrenoceptors.

MAOI = monoamine oxidase inhibitor.

Sympathomimetics. Direct-acting agents. Xenobiotics whose sympathomimetic actions result from direct binding to α -adrenergic receptors or β -adrenergic receptors are called direct-acting sympathomimetics. Most do not cross the blood–brain barrier in significant quantities.

Indirect-acting agents. Xenobiotics that produce sympathomimetic effects by causing the release of cytoplasmic NE from the nerve ending in the absence of vesicle exocytosis are called indirect-acting sympathomimetics. Amphetamine is the prototype of indirect-acting sympathomimetics and is used for the discussion of what is known about their mechanisms of action.²⁹ In general, mechanisms of indirect release of NE by amphetamines, cocaine, phencyclidine, MAOIs, and mixed-acting xenobiotics noted in Table 14–4 are similar in that their actions depend on their ability to produce elevated cytoplasmic NE concentrations.

Amphetamine and structurally similar indirect-acting sympathomimetics move into the neuron mainly by the membrane transporter that transports NE into the neuron. Lipophilic indirect-acting sympathomimetics may also move into the neuron by diffusion. From the cytoplasm, amphetamines are transported into neurotransmitter vesicles, where they buffer protons to raise intravesicular pH. As noted earlier, much of the vesicle's ability to concentrate NE (and other neurotransmitters) is a result of ion trapping of NE at the lower pH. The rise in intravesicular pH produced by amphetamines causes NE to leave the vesicle and move into the cytoplasm.^{197,198} This movement may be caused by diffusion or reverse transport of NE by VMAT2. In the cytoplasm, amphetamines also compete with NE and DA for transport into vesicles, which further contributes to elevated cytoplasmic NE concentrations. In the case of amphetamine, the rise in cytoplasmic concentrations of NE may be further enhanced by the ability of amphetamine metabolites to inhibit MAO, which impairs NE degradation.

Every time the Na^+ -dependent uptake transporter, NET, moves a bioactive amine (eg, tyramine) into the neuron where it is released, a binding site for NE on NET conceptually transiently faces inward and becomes available for reverse transport of NE out of the neuron. The normally low concentration of cytoplasmic NE prevents significant reverse transport. In the face of elevated cytoplasmic NE concentrations produced by indirect-acting sympathomimetics, NET moves NE out of the neuron and back into the synapse, where the neurotransmitter stimulates adrenergic receptors (indirect action). This process is sometimes referred to as facilitated exchange diffusion, or displacement, of NE from the nerve ending. Evidence supporting reverse transport produced by amphetamines is that inhibitors of the transporter (eg, tricyclic antidepressants) prevent amphetamine-induced NE release.

While all indirect-acting sympathomimetics cause reverse NE transport by increasing cytoplasmic NE concentrations, those that move into the neuron by the membrane transporter (eg, amphetamines, MAOIs, DA, tyramine) further enhance reverse transport because their uptake may cause more NE-binding sites on NET to face inward per unit time.

Although cocaine inhibits NET, it also causes some NE release. In fact, cocaine similarly lessens pH gradients across vesicle membranes to raise cytoplasmic concentrations of NE.¹⁹⁸ That cocaine produces less NE release than amphetamines is partly explained by cocaine-induced inhibition of the membrane transporter and possibly by the fact that cocaine does not move into the neuron by active uptake (ie, does not increase the number of NE-binding sites facing inward), but diffuses into the neuron. In fact, most of cocaine's severe sympathomimetic effects may result from its action on the brain rather than peripheral nerve endings.²⁰⁵

Phencyclidine (PCP) is a hallucinogen that possesses multiple pharmacologic actions. Like toxicity from many

hallucinogens, PCP toxicity is accompanied by increased adrenergic activity, which results, in part, from PCP-induced decreases in pH gradients across the vesicle membrane¹⁹⁸ and indirect release of NE. Like cocaine, PCP moves into the neuron by diffusion rather than uptake through the membrane transporter, at least partly explaining less PCP-induced NE release than typically occurs in amphetamine poisoning.

In addition to causing ACh release, black widow spider venom causes vesicle exocytosis of NE, producing hypertension and diaphoresis over the palms, soles, upper lip, and nose. All of the aforementioned indirectly acting sympathomimetics, except black widow spider venom, enter the CNS.

Mixed-acting agents. Mixed-acting sympathomimetics act directly and indirectly. For example, ephedrine indirectly causes NE release and directly activates adrenergic receptors. Intravenously administered DA indirectly causes NE release, explaining most of its vasoconstricting activity, but also directly stimulates dopaminergic and β -adrenergic receptors. Direct α -agonism occurs at high doses. Except for DA, these xenobiotics cross the blood–brain barrier to produce central effects.

Reuptake inhibitors. Inhibitors of NE reuptake raise concentrations of NE in the synapse to produce excessive stimulation of adrenergic receptors.

There are two main means by which inhibitors of bioactive amine inhibit reuptake: competitive and noncompetitive. Noncompetitive inhibitors, such as cyclic antidepressants, carbamazepine, venlafaxine, methylphenidate, and cocaine, bind at or near the carrier site on NET to prevent NET from moving NE and similar xenobiotics into or out of the neuron. Various xenobiotics used for their antimuscarinic effects also block NET noncompetitively. These include benztropine, diphenhydramine, trihexyphenidyl, and orphenadrine.¹³⁹ Atomoxetine also inhibits NET.

The second mechanism, competitive inhibition of NET, characterizes most indirect-acting sympathomimetics, including amphetamines and structurally similar xenobiotics (eg, mixed-acting agents, MAOIs). These xenobiotics prevent NE reuptake by competing with synaptic NE for binding to the carrier site on NET, a mechanism by which they can move into the neuron. In fact, an additional adrenergic action of amphetamines, mixed-acting agents, MAOIs, and tyramine is to raise synaptic NE concentrations by competing for uptake, thereby compounding their indirect or direct actions.

MAOIs. MAOIs are transported by NET into the neuron, where they act through several mechanisms (Table 14–4).^{1,127} Inhibition of MAO, their main pharmacologic effect, results in increased cytoplasmic concentrations of NE and some indirect release of neurotransmitter into the synapse. As a minor effect they also may displace NE from vesicles by raising pH in a manner similar to amphetamines. These actions explain the initial sympathomimetic findings following MAOI overdose and may also account for occasional and unpredictable adrenergic crises that occur despite dietary compliance.

Nonspecific MAOIs inhibit both isoenzymes of MAO, preventing intestinal and hepatic degradation of bioactive amines. A person taking such an MAOI who then is exposed to indirect-acting sympathomimetics (eg, tyramine in cheese, ephedrine, DA, amphetamines) has a much larger cytoplasmic concentration of NE to transport into the synapse and may, therefore, develop central and peripheral sympathomimetic findings. MAOIs specific for the MAO-B isozyme are less likely to predispose to food or drug interactions by maintaining significant hepatic and intestinal MAO activity. Furthermore, reversible MAO-A specific inhibitors are also less likely to provoke this reaction because their reversibility allows competition of exogenous amines with the inhibitor, resulting in its displacement from the enzyme and normal metabolism of the bioactive amines.²¹⁹ Isozyme specificity may be lost as the dose of the MAOI is increased. In fact, selegiline, currently marketed as a selective MAO-B inhibitor, partially inhibits MAO-A activity at therapeutic doses. Rasagiline is a newer MAO-B inhibitor that has 100-fold greater affinity for MAO-B than MAO-A, but still loses specificity at supratherapeutic doses.^{69,79} MAOI isozyme specificity may also be of low importance when indirect-acting agents are administered parenterally (eg, intravenous DA or amphetamines). Linezolid is an antibiotic that displays nonspecific MAO inhibition,¹⁴⁶ while methylene blue mainly inhibits MAO-A.¹⁷⁷

Occasionally, patients suffering from refractory depression respond to a combination of MAOIs and tricyclic antidepressants. This combination therapy is usually unaccompanied by excessive adrenergic activity because the inhibition of the membrane uptake transporter by the tricyclic antidepressant attenuates excessive reverse transport of elevated cytoplasmic NE concentrations produced by MAOIs.

COMT inhibitors. Inhibitors of COMT are administered in the treatment of Parkinson disease to prevent the catabolism of concomitantly administered L-dopa. Entacapone only acts peripherally, whereas tolcapone also crosses the blood–brain barrier where it can also prevent DA degradation as well.

α_2 -Adrenergic receptor antagonists. Yohimbine produces selective competitive antagonism of α_2 -adrenergic receptors to produce a mixed clinical picture. Peripheral postsynaptic α_2 blockade produces vasodilation. Blockade of presynaptic α_2 -adrenergic receptors on cholinergic nerve endings (Fig. 14–4) enhances ACh release, occasionally producing bronchospasm¹⁰² and contributing to diaphoresis. Similar presynaptic actions on peripheral noradrenergic nerves enhance catecholamine release (Fig. 14–5). Antagonism of central α_2 -adrenergic receptors in the locus ceruleus results in CNS stimulation, whereas blockade of postsynaptic α_2 -adrenergic receptors in the nucleus tractus solitarius may enhance sympathetic output (Fig. 14–6). The final result includes hypertension, tachycardia, anxiety, fear, agitation, mania,

mydriasis, diaphoresis, and bronchospasm.¹¹¹

Sympatholytics. Direct antagonists. Direct α -adrenergic receptor and β -adrenergic receptor antagonists are noted in Table 14–5. After overdose, β -adrenergic receptor selectivity may be less significant. Some β -adrenergic receptor antagonists also are partial agonists.

Xenobiotics that prevent norepinephrine release. Xenobiotics that block the vesicle uptake transporter prevent the movement of NE into vesicles and deplete the nerve ending of this neurotransmitter, preventing NE release after depolarization. Reserpine and ketanserin inhibit both VMAT1 and VMAT2, whereas tetrabenazine only inhibits VMAT2. Like guanethidine, reserpine causes transient NE release with the initial dose or early in overdose. β -Adrenergic receptor antagonists block presynaptic β_2 -adrenergic receptors to limit catecholamine release from nerve endings, although most of the antihypertensive action of β -adrenergic antagonists at therapeutic doses results from inhibition of renin release in the kidney.

α_2 -Adrenergic receptor agonists. Numerous imidazoline derivatives (eg, clonidine) and structurally similar xenobiotics used as centrally acting antihypertensives or long-acting topical vasoconstrictors act by activating α_2 -adrenergic receptors. These xenobiotics also display various affinities for what are termed imidazoline-binding sites, apart from α_2 -adrenergic receptors. Although imidazoline-binding sites have been proposed and subdivided into I₁, I₂, and I₃,⁵¹ and endogenous ligands for these binding sites have been discovered (eg, agmatine, imidazole-acetic acid ribotide, harmaline, other β -carbolines),^{16,73,167} it must be recognized that the molecular structures of imidazoline-binding sites have not been determined, nor have signaling pathways been characterized. As a result, major professional societies such as The International Union of Pharmacology Committee on Receptor Nomenclature and Drug Classification have not adopted the term imidazoline receptor.¹⁰⁸ The role of imidazoline-binding sites in mediating responses to xenobiotics remains controversial and ill defined.

The ventromedial (depressor) and the rostral-ventrolateral (pressor) areas of the ventrolateral medulla (VLM) are responsible for the central regulation of cardiovascular tone and blood pressure. They receive afferent fibers from the carotid and aortic baroreceptors, which form the tractus solitarius via the nucleus tractus solitarius (NTS).⁹⁴

Ingestions of xenobiotics that activate α_2 -adrenergic receptors (Table 14–5) produce a mixed clinical picture. Peripheral postsynaptic α_2 -adrenergic receptor stimulation produces vasoconstriction, pallor, and hypertension, often with reflex bradycardia (Fig. 14–5). Peripheral presynaptic α_2 -adrenergic receptor stimulation prevents NE release (Fig. 14–5), reducing sympathetic activation. Central α_2 -adrenergic receptor stimulation in the locus ceruleus accounts for CNS and respiratory depression (Fig. 14–6). Recently acquired knowledge about α_2 -adrenergic receptor subtypes and their effects on non-adrenergic neurons makes analysis of their hypotensive and sedative effects complex. Recent animal evidence supports that sedation is not entirely mediated by α_2 -adrenergic receptor activation on noradrenergic neurons in the locus ceruleus.⁶⁷ Stimulation of postsynaptic α_{2A} -adrenergic receptors in the NTS in the VLM is thought to inhibit sympathetic output and enhance parasympathetic tone, explaining hypotension with bradycardia (Fig. 14–6).⁹⁴

Dopamine- β -hydroxylase inhibition. Inhibition of dopamine- β -hydroxylase, a copper-containing enzyme (Fig. 14–5), prevents the conversion of DA to NE, resulting in less NE release and less α - and β -adrenergic receptor stimulation. Disulfiram and diethyldithiocarbamate, copper chelators, produce such inhibition.⁵³ Because NE release mediates most of the ability of DA to cause vasoconstriction, NE is the vasopressor of choice in a hypotensive patient taking disulfiram. MAOIs and α -methyl dopa also inhibit dopamine- β -hydroxylase, although this is not their main mechanism of action.¹²⁷

Dopamine is relatively contraindicated in hypotensive patients who have overdosed on MAOIs. First, DA acts indirectly, and its administration might produce excessive adrenergic activity and exaggerated rises in blood pressure. Second, even if an adrenergic storm does not occur, most of the α -mediated vasoconstriction of dopamine is secondary to NE release. In the presence of MAOIs, NE synthesis may be impaired from concomitant dopamine- β -hydroxylase inhibition, and DA may not reliably raise blood pressure if cytoplasmic and vesicular stores have been depleted. In the presence of impaired NE release or α -adrenergic receptor blockade by any cause, unopposed dopamine-induced vasodilation from action on peripheral DA and β -adrenergic receptors may paradoxically lower blood pressure further. Norepinephrine and EPI can be used to support blood pressure relatively safely in patients taking MAOIs because they have little or no indirect action and are metabolized by COMT when given intravenously.

DOPAMINE

Because DA is the direct precursor of NE, noradrenergic vesicles contain DA. The release of NE from peripheral sympathetic nerves, therefore, always results in release of some DA (Fig. 14–5), as does the release of NE and EPI from the adrenal gland, explaining most of DA in blood. In peripheral tissues, activation of DA receptors causes vasodilation of renal, mesenteric, and coronary vascular beds. Dopamine can also stimulate β -adrenergic receptors and, at high doses, can directly stimulate α -adrenergic receptors. When DA is administered intravenously, most vasoconstriction is caused by

dopamine-induced NE release.

Dopamine accounts for about one-half of all catecholamines in the brain and is present in greater quantities than NE or 5-HT. By contrast to the diffuse projections of noradrenergic neurons, dopaminergic neurons and receptors are highly organized and concentrated in several areas, especially in the basal ganglia and limbic system.^{100,178}

Excessive dopaminergic activity in the striatum and/or other areas from any cause (eg, increased release, impaired uptake, increased receptor sensitivity) can produce acute choreoathetosis⁹⁶ and acute Gilles de la Tourette syndrome, with tics, spitting, and cursing. Excessive dopaminergic activity in the limbic system and frontal cortex, and perhaps in other areas, produces paranoia and psychosis. Dopaminergic activity in the nucleus accumbens and is thought responsible for much of the drug craving and addictive behavior in patients abusing sympathomimetics, opioids, alcohol, and nicotine. Diminished dopaminergic tone (eg, impaired release, receptor blockade) in the striatum produces various extrapyramidal disorders such as acute dystonias and parkinsonism.^{166,192,208}

Synthesis, Release, and Reuptake

The steps of DA synthesis and vesicle storage are the same as those for NE, except that DA is not converted to NE after transport into vesicles (Fig. 14–7). Dopamine is removed from the synapse via reuptake by DAT, the membrane-bound DA transporter. DAT and NET exhibit 66% homology in their amino acid sequences. Like NET, DAT is not completely specific for DA and transports amphetamines and other structurally similar sympathomimetics. Cytoplasmic DA has a fate similar to NE. It is pumped back into vesicles by VMAT2 (brain) and VMAT1 (neuroendocrine tissue, adrenal glands) or degraded by MAO and COMT.

FIGURE 14–7. A dopaminergic nerve ending and postsynaptic membrane. Dopamine (DA) released from nerve endings binds to various postsynaptic DA receptors (D) on neurons or peripheral end organs. Stimulation of presynaptic D₂ receptors [9] lessens DA release. Xenobiotics in Table 14–6 may act to inhibit vesicle uptake [1]; cause DA to leave the

vesicle and move into the cytoplasm [2]; activate or antagonize DA receptors [3, 4, 9]; inhibit DAT to prevent DA reuptake [5]; cause reverse transport of cytoplasmic DA (via DAT) into the synapse by raising cytoplasmic DA concentrations [6]; prevent DA degradation by inhibiting monoamine oxidase (MAO) [7]; or prevent DA degradation by inhibiting catechol-O-methyltransferase (COMT) [8]. (Both DA and dopa are substrates for COMT.) Inhibition or stimulation of adenylate cyclase by DA receptors is shown for illustration, though other G-protein-mediated effects can result. AADC = L-aromatic amino acid decarboxylase; DAT = membrane DA reuptake transporter; DOPAC = 3,4-dihydroxyphenylacetic acid; VMAT2 = vesicle membrane uptake transporter.

DOPAMINE RECEPTORS

All DA receptors are coupled to G proteins and are divided into two main groups. Dopamine D₁-like receptors (D₁ and D₅) are expressed as various subtypes and are linked to G_s to stimulate adenylate cyclase and to raise cAMP concentrations.¹⁸¹ D₁ receptors are found in the nuclei of the basal ganglia and the cerebral cortex, and D₅ receptors are concentrated in the hippocampus and hypothalamus. Dopamine is five to 10 times more potent at D₅ receptors than it is at D₁ receptors.

D₂-like receptors (D₂, D₃, D₄) are linked to G_{i/o} to produce several actions, including inhibition of adenylate cyclase and the lowering of cAMP concentrations. Again, numerous subtypes of receptors exist (eg, D_{2s}, D_{2L}). D₂ receptors are concentrated in the basal ganglia and limbic system. Some D₂ receptors also reside on presynaptic membranes, where their activation limits neurotransmitter release, including the peripheral release of NE (Figs. 14–5 and 14–7). D₃ receptors are concentrated in the hypothalamic and limbic nuclei, whereas D₄ receptors are concentrated in the frontal cortex and limbic nuclei (rather than basal ganglia nuclei). Most agonists bind to the D₃ receptors with higher affinity than to D₂ receptors, whereas most antagonists bind preferentially to D₂ receptors.^{100,178} Most agonists and antagonists express a lower affinity for D₄ receptors than they express for D₂ receptors; a notable exception is clozapine.

Xenobiotics

Table 14–6 provides examples of xenobiotics that affect dopaminergic neurotransmission.

^aAssociated with fibrotic valvulopathy due to 5-HT_{2B} agonism. ^bMetabolized to dopamine, which acts as an agonist.

COMTI = catechol-o-methyltransferase inhibitor; MAOI = monoamine oxidase inhibitor; MPTP = 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; MPP⁺ = 1-methyl-4-phenylpyridinium.

Dopamine Agonism. Indirect-acting and mixed-acting xenobiotics. Most indirect-acting and mixed-acting sympathomimetics cause DA release. The mechanism of action is similar to that causing NE release. These xenobiotics diffuse into the neuron or undergo uptake by DAT before being transported into vesicles by VMAT2 where they buffer protons and displace DA into the cytoplasm for reverse transport by DAT into the synapse. Benztropine, diphenhydramine, trihexyphenidyl, and orphenadrine also cause DA release, perhaps contributing to their abuse potential, which is noted below.¹³⁹ Excessive dopaminergic activity following therapeutic doses or overdoses of decongestants (eg, pseudoephedrine), amphetamines, methylphenidate, and pemoline can produce acute choreoathetosis and Gills de la Tourette syndrome.^{25,116} Ingestion of excessive doses of L-dopa (which is converted to DA) may present with similar symptoms.

Direct agonists. Bromocriptine is an ergot derivative that directly activates DA receptors (mainly D₂-like). Toxic effects include those described above for indirect-acting agents. Apomorphine directly activates D₂ receptors. Such action at the chemoreceptor trigger zone (CTZ) produces vomiting, whereas agonism in the basal ganglia explains the use of apomorphine in the treatment of Parkinson disease. Fenoldopam is a D₁ receptor agonist that is used as a vasodilator in the treatment of hypertensive emergencies.

D₁-like and D₂-like receptor activation is the predominant mediator of locomotor effects from DA agonists. Activation of either D₁-like or D₂-like receptors produces antiparkinsonian effects.^{76,178} Cabergoline, ropinirole, and pramipexole are D₂-like receptor agonists used to treat Parkinson disease.^{11,51,71}

Reuptake inhibition. Xenobiotics inhibiting DAT prevent DA reuptake and include cocaine, amphetamines, methylphenidate, and probably amantadine. Increased dopaminergic activity from cocaine toxicity may produce choreoathetosis and Gills de la Tourette syndrome. In general, antidepressants are not strong DA reuptake blockers. However, bupropion appears to be more active in this regard.¹⁷³

As noted earlier, much of the craving and addiction produced by sympathomimetics probably results from excessive dopaminergic activity in the mesolimbic system.¹⁹² Interestingly, the anticholinergics benztropine, diphenhydramine, trihexyphenidyl, and orphenadrine are also DA reuptake inhibitors, possibly explaining their abuse potential.^{139,188} In fact, benztropine is one of the most potent DA reuptake inhibitors known. Amantadine, an antiparkinsonian drug that causes DA release and some inhibition of DA reuptake (as well as being anticholinergic), is also abused.

Increased receptor sensitivity. Several xenobiotics are thought to increase sensitivity of DA receptors, resulting in choreoathetosis, even with therapeutic doses (eg, phenytoin). Evidence exists that increased DA receptor sensitivity may be

responsible for movement disorders resulting from amphetamines.²⁸ Tardive dyskinesia (discussed below) may also result from increased DA receptor sensitivity and occurs following chronic administration of D₂ receptor antagonists.

MAO inhibition. MAOIs inhibit the breakdown of cytoplasmic DA. Some of the food and drug interactions with MAOIs result from excessive release of DA from nerve endings.

COMT inhibition. COMT inhibitors (eg, entacapone, tolcapone) are given with levodopa to patients with Parkinson disease to prevent peripheral degradation of levodopa to 3-O-methyldopa. This allows more levodopa to traverse the blood–brain barrier and to be converted to DA by neuronal dopa decarboxylase. Tolcapone also inhibits COMT in the brain.⁸⁹ Other substrates of COMT include dopa, DA, NE, EPI, and their hydroxylated metabolites. COMT inhibitors might potentiate the effects of these drugs when administered intravenously.⁸⁹

Dopamine Antagonism. **Direct receptor blockade.** Blockade of DA receptors is the specific aim of many therapeutics. The antipsychotic actions of butyrophenones, phenothiazines, and other antipsychotics mainly correlate with their ability to block D₂-like receptors. Many phenothiazines block both D₁-like and D₂-like receptors, whereas haloperidol mainly blocks D₂-like receptors. Unfortunately, antipsychotics and metoclopramide also block DA receptors in the striatum, producing various extrapyramidal symptoms, including acute parkinsonism and dystonias.

Atypical antipsychotics produce fewer extrapyramidal effects and are thought to carry less risk of producing tardive dyskinesia.¹⁷⁰ The relative affinity of an antipsychotic for 5-HT_{2A} receptors over D₂ receptors has predictive value for atypicals with a lower risk of extrapyramidal symptoms.¹⁶⁰ These include clozapine, olanzapine, quetiapine, risperidone, and ziprasidone.

The ratio of muscarinic (M₁) blockade to D₂-receptor blockade is also important in limiting extrapyramidal symptoms. Antipsychotics exhibiting strong antimuscarinic effects (eg, olanzapine, clozapine, thioridazine) are also less likely to induce extrapyramidal symptoms.¹⁷⁰

Buspirone, an anxiolytic, antagonizes D₂ receptors, which explains occasional extrapyramidal reactions. Various cyclic antidepressants, especially amoxapine, block D₂ receptors to some extent.

The chronic use of dopamine receptor antagonists causes upregulation of DA receptors. The continued use of or, especially, withdrawal of DA receptor antagonists (antipsychotics, metoclopramide, and occasionally antidepressants) can result in excessive dopaminergic activity and tardive dyskinesia, characterized by choreiform movements typical of excessive dopaminergic influence in the striatum.

The blockade of DA receptors by numerous xenobiotics, including butyrophenones, phenothiazines, and metoclopramide, can produce a poorly understood disorder called neuroleptic malignant syndrome. Neuroleptic malignant syndrome may also rarely follow acute withdrawal of DA agonists (eg, stopping L-dopa, bromocriptine, or tolcapone). Neuroleptic malignant syndrome is characterized, in part, by mental status changes, autonomic instability, rigidity, and hyperthermia.

Indirect Antagonism. Reserpine and tetrabenazine inhibit VMAT to prevent transport of DA into storage vesicles and deplete nerve endings of DA. In fact, reserpine was used as an antipsychotic before the introduction of phenothiazines. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a meperidine analog, undergoes activation by MAO, including that in glial cells, to a metabolite, 1-methyl-4-phenylpyridinium (MPP⁺), that undergoes uptake by and causes death of dopaminergic neurons. Both MAOIs and inhibitors of DA transporters prevent MPTP-induced destruction of dopaminergic neurons.

SEROTONIN

Serotonin (5-HT, 5-OH-tryptamine) is an indole alkylamine found throughout nature (animals, plants, venoms) and has the most complex receptor family of all known neurotransmitters. In the CNS, several hundred thousand serotonergic neurons lie in or in juxtaposition to numerous midline nuclei in the brainstem (raphe nuclei), from which they project to virtually all areas of the brain and spinal cord. Serotonin is involved with mood, emotion, learning, memory, personality, affect, appetite, aggression, motor function, temperature regulation, sexual activity, pain perception, sleep induction, and other basic functions. Serotonin is not essential for any of these processes, but modulates their quality and extent. A number of psychiatric disorders, including depression, anxiety, obsessive-compulsive disorder, dementia, schizophrenia, and eating disorders, are linked to altered serotonin function. Consequently, modification of serotonergic neurotransmission is an integral part of the treatment plan for most of these conditions.¹⁶⁵

The serotonergic system is extremely diverse, with 14 types of receptors that act to stimulate or inhibit neurons, including those of other neurotransmitter systems. Serotonin is also the precursor for the pineal hormone, melatonin. Despite the important role 5-HT plays in the CNS, less than 5% of the body's 5-HT is found within the CNS, with the great majority of 5-HT being located within enterochromaffin cells of the intestine and a small amount of serotonin sequestered by platelets.¹⁵

Peripherally, 5-HT is released by enterochromaffin cells in response to intestinal stimulation, which contributes to peristalsis and fluid secretion. Platelets take up 5-HT while passing through the enteric circulation. Serotonin is released from activated platelets to interact with other platelet membranes (promote aggregation) and with vascular smooth muscle.¹⁵

Experimentally, 5-HT exhibits diverse effects on the cardiovascular and peripheral nervous systems, although the importance of these actions remains uncertain in the normal physiologic state. Serotonin-induced vasoconstriction or vasodilation found in experimental studies involves multiple types of 5-HT receptors and, in turn, is influenced by multiple other factors. 5-HT_{1B} receptor agonists (eg, sumatriptan) produce coronary artery vasoconstriction in some patients as an adverse event.^{147,210}

Centrally, it is particularly difficult to ascribe a specific symptom or physical finding to serotonergic neurons because of the diversity of their physiologic actions. However, 5-HT definitely plays an important role in the action of many hallucinogenic or illusionogenic drugs, which act as partial agonists at cortical 5-HT₂ receptors. Proserotonergics are used to treat depression, whereas 5-HT receptor (5-HT₂) antagonists have greater importance in the management of schizophrenia.⁶⁴

Generally, in areas where they overlap, 5-HT acts in opposition to DA. For example, 5-HT serves to increase prolactin, adrenocorticotrophic hormone (ACTH), and growth hormone secretion, whereas DA decreases prolactin secretion. As another example, activation of basal ganglial 5-HT_{2A} receptors inhibits DA release.⁶⁴ However, well-known exceptions exist, such as cortical 5-HT₃ receptors³¹ and 5-HT_{1A} receptors that are capable of promoting DA release under certain circumstances.¹⁴⁴

Synthesis, Release, and Reuptake

Serotonin does not cross the blood–brain barrier. It is synthesized from the amino acid Ltryptophan, which passes through the blood–brain barrier using a neutral amino acid transporter. **Figure 14–8** illustrates 5-HT synthesis. Tryptophan-5-hydroxylase is the rate-limiting enzyme of 5-HT synthesis. Increases in tryptophan are predictably accompanied by increased 5-HT production. L-Amino acid decarboxylase (dopa decarboxylase) converts 5-hydroxytryptophan to 5-HT. Cytoplasmic 5-HT is transported into vesicles by VMAT2, where it is concentrated by ion trapping before release by Ca²⁺-dependent exocytosis. In contrast to vesicles containing DA or NE, 5-HT vesicles contain almost no ATP. After release into the synapse, a transporter (SERT) in the neuronal membrane moves 5-HT back into the neuron, where it reenters vesicles or is degraded by MAO.¹⁶⁵

FIGURE 14–8. A serotonergic nerve ending and postsynaptic membrane. Tryptophan hydroxylase [1] converts tryptophan to 5-hydroxytryptophan (5-OH-tryptophan). Aromatic L-amino acid decarboxylase (AADC) then metabolizes 5-OH-tryptophan to serotonin (5-HT). Serotonin is concentrated within vesicles through uptake by VMAT2 before exocytosis [2]. After uptake into the neuron by SERT [7], 5-HT is transported back into vesicles or undergoes degradation by monoamine oxidase (MAO) to an intermediate compound, which is converted to 5-hydroxyindoleacetic acid (5-HIAA) [8]. 5-HT_{1,2,4,6,7} receptors [3,9,10] are coupled to G proteins, while 5-HT₃ receptors [4] are ligand-gated cation channels that may conduct Na⁺ and/or Ca²⁺ (only Na⁺ is illustrated). 5-HT₃ cation channels also appear to be blocked by Mg²⁺ until the cell is depolarized, allowing Mg²⁺ to dissociate—a mechanism similar to that found at NMDA glutamate receptors. In addition to residing on postsynaptic membranes, 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{1D} receptors serve as presynaptic autoreceptors that, when stimulated, decrease further release of 5-HT [9,10]. Presynaptic 5-HT_{1A} receptors mainly serve as somatodendritic autoreceptors, whereas presynaptic 5-HT_{1B} and 5-HT_{1D} receptors serve as terminal autoreceptors. Xenobiotics in Table 14–7 act to enhance 5-HT synthesis [1]; inhibit VMAT2 to prevent vesicle uptake of 5-HT [2]; raise cytoplasmic concentrations of 5-HT, resulting in reverse transport of 5-HT into the synapse by SERT [6]; by displacing 5-HT from vesicles [5] or inhibiting MAO [8]; activate or antagonize 5-HT receptors [3,4,9,10]; or by inhibiting 5-HT reuptake [7]. G = G protein; SERT = membrane 5-HT uptake transporter; VMAT2 = vesicle membrane uptake transporter.

Serotonin is preferentially metabolized by the MAO-A isozyme. Paradoxically, the serotonergic nerve terminal is almost devoid of MAO-A, but contains abundant amounts of MAO-B. It has been hypothesized that the large amounts of MAO-B metabolize other xenobiotics that might inappropriately promote 5-HT release (eg, dopamine). However, the small amount of MAO-A found in serotonergic neurons provides adequate degradation of 5-HT.¹⁴²

Serotonin Receptors

There are seven major functioning receptor types (5-HT₁–5-HT₇) and numerous subtypes.

5-HT₁ Receptors. Receptors in the 5-HT₁ class are coupled to G proteins and commonly increase K⁺ efflux and decrease cAMP concentrations. Members of the 5-HT₁ receptor class express greatest affinity for 5-HT and are thus

biologically active under normal physiologic conditions. 5-HT_{1A} receptors reside predominantly on raphe nuclei, where they act as somatodendritic autoreceptors.^{101,132,151} Hippocampal 5-HT_{1A} receptors reside postsynaptically, where they also inhibit through similar mechanisms.¹⁰¹

Central 5-HT_{1D} and 5-HT_{1B} receptors primarily act as inhibitory terminal autoreceptors and heteroreceptors. They are found less commonly on postsynaptic membranes.¹⁶⁵ Originally 5-HT_{1B} receptors were not believed to exist in humans. However, most of the actions described in older literature regarding 5-HT_{1D} receptors can now be attributed to 5-HT_{1B} receptors. Cranial blood vessels (eg, meninges) possess 5-HT_{1D} and 5-HT_{1B} receptors, whose activation produces vasoconstriction and decreased inflammation.^{147,165}

5-HT_{1E} and 5-HT_{1F} receptors are more recently discovered members of the 5-HT₁ receptor class. Their functional activity is yet to be determined.

5-HT₂ Receptors. The three subtypes of 5-HT₂ receptors are coupled to G proteins, thus serving to decrease K⁺ efflux and/or increase intracellular Ca²⁺ concentration by raising concentrations of inositol triphosphate and diacylglycerol.¹⁶⁵ The three subtypes of 5-HT₂ receptors are so similar in characterization that investigational probes have great difficulty in distinguishing the subtypes. 5-HT_{2A} receptors are most concentrated in the cerebral cortex, where they serve as excitatory postsynaptic receptors. Their activation increases glutamate release from pyramidal cells, but also can lead to release of GABA.¹³⁰ 5-HT_{2A} receptors also reside on platelets, where their activation produces platelet aggregation. 5-HT_{2C} receptors (previously 5-HT_{1C}) reside on the choroid plexus, where they regulate cerebrospinal fluid production. Activation of 5-HT_{2B} receptors in the GI tract promotes stomach contraction.¹⁶⁵ At least some xenobiotics that activate 5-HT_{2B} receptors on cardiac valves cause a valvulopathy identical to that of carcinoid syndrome, though both sides of the heart can be involved following 5-HT_{2B} agonists, whereas carcinoid syndrome usually affects the right sided valves.²⁴

5-HT₃ Receptors. 5-HT₃ receptors are isopentameric ligand-gated cation channels that are structurally similar to ACh nicotinic receptors, GABA_A Cl⁻ channels, glycine, and NMDA glutamate receptors.³¹ They are localized to both presynaptic and postsynaptic membranes. Upon activation, postsynaptic receptors stimulate the neuron by opening the channel to cause depolarization through Na⁺ and/or Ca²⁺ influx. In addition, these channels are normally blocked by Mg²⁺ in a voltage-dependent manner similar to glutamatergic NMDA receptors (see Glutamate later). Centrally, 5-HT₃ receptors are expressed diffusely, but are especially concentrated in the CTZ, where their activation induces emesis.¹⁶⁵ In the cerebral cortex, their activation leads to increased release of DA and decreased release of ACh.³¹ Cortical 5-HT₃ receptors are frequently identified on GABA interneurons where they increase inhibitory, GABAergic tone. In contrast to cerebral actions, activation of peripheral 5-HT₃ receptors on cholinergic nerves in the gut enhances ACh release to increase gastrointestinal motility.¹⁴⁰

5-HT₄ Receptors. 5-HT₄ receptors are coupled to G proteins (G_s). Their activation leads to increased cAMP concentrations. 5-HT₄ receptors are scattered diffusely throughout the brain, and their exact role remains undefined, although they are known to increase the release of ACh.¹⁴⁰ Peripheral 5-HT₄ receptors reside in the heart, intestines, and adrenal gland where their activation produces tachycardia, aldosterone and cortisol release, and contraction of gut and bladder smooth muscle. Whether these actions are important under normal physiologic conditions is not clear, but peripheral 5-HT₄ receptors promote the release of ACh and increase gut motility.¹⁴⁰

5-HT₅ Receptors. 5-HT₅ receptors exist in two subtypes: 5-HT_{5a} and 5-HT_{5b}. Humans only have the 5-HT_{5a} subtype, which is coupled to G_{i/o}.¹⁶⁵ This receptor may act as a somatodendritic autoreceptor but the functionality of this role is unknown, in contrast to the predominant importance of 5-HT_{1a} autoreceptors.

5-HT₆ and 5-HT₇ Receptors. 5-HT₆ and 5-HT₇ receptors are positively coupled to cAMP formation through G proteins.¹⁶⁵ Their distribution is poorly defined. However, many antidepressants and antipsychotics antagonize these receptors. They are currently a source of great interest because of the possibility of avoiding DA blockade to achieve antipsychotic activity. The 5-HT₇ receptor may be particularly important in regulating circadian rhythms.¹⁰⁶

Xenobiotics

Table 14–7 provides examples of xenobiotics that affect serotonergic neurotransmission.

TABLE 14–7. Examples of Xenobiotics Affecting Serotonergic Neurotransmission

Serotonin Agonism

Enhance 5-HT synthesis

l-Tryptophan

5-Hydroxytryptophan

Direct 5-HT agonists

Buspirone

Cisapride

Ergots and indoles

Hallucinogenic substituted amphetamines

mCPP

Lisuride

Mescaline

Metoclopramide

Triptans

Vilazodone

Increase 5-HT release

Amphetamine

Cocaine

Dexfenfluramine

Dextromethorphan

l-Dopa

Fenfluramine

MDMA

Mirtazapine

Reserpine (initial)

Increase 5-HT tone by unknown mechanism

Lithium

Inhibit 5-HT breakdown

MAOIs

Inhibit 5-HT reuptake

Amoxapine

Amphetamines

Atomoxetine

Carbamazepine

Citalopram

Clomipramine

Cocaine

Cyclic antidepressants

Dextromethorphan

Duloxetine

Escitalopram

Fluoxetine

Fluvoxamine

Lamotrigine

Meperidine

Nefazodone

Sertraline

Tramadol

Trazodone

Venlafaxine Vilazodone

Serotonin Antagonism

Direct 5-HT antagonists

Agomelatine

Aripiprazole

Clozapine

Cyclic antidepressants

Cyproheptadine

Ergots and indoles (eg, LSD)

Haloperidol

Ketanserin

Mescaline

Methysergide

Metoclopramide

Mirtazapine

Nefazodone

Olanzapine
Ondansetron
Paliperidone
Phenothiazines
Phentolamine
Propranolol
Quetiapine
Risperidone
Trazodone
Ziprasidone
Enhance 5-HT uptake
Tianeptine
Inhibit vesicle uptake
Reserpine
Ketanserin
Tetrabenazine

^aClomipramine is the most potent 5-HT uptake inhibitor of the tricyclic antidepressants.

5-HT, serotonin; LSD = lysergic acid diethylamide; MAOI = monoamine oxidase inhibitor; mCPP = m-chlorophenylpiperazine (metabolite of trazodone and nefazodone); MDMA = methylenedioxymethamphetamine.

Serotonin Agonists. The body rapidly metabolizes orally administered 5-HT via intestinal and hepatic MAO. However, L-tryptophan is an amino acid precursor to 5-HT that is readily absorbed by the intestinal tract. This method of augmenting CNS 5-HT production was previously used as an unproved sleep aid until it was associated with the eosinophilia myalgia syndrome in 1990. 5-Hydroxytryptophan (5-HTP) is the immediate precursor to 5-HT. 5-HTP is commonly available without a prescription. The anxiolytics, buspirone, gepirone, and ipsapirone act as partial agonists at somatodendritic and postsynaptic 5-HT_{1A} receptors. Sumatriptan, an antimigraine medication, mainly activates 5-HT_{1D} and 5-HT_{1B} receptors.¹⁴⁷ The action of sumatriptan may result from vasoconstriction of meningeal and other cranial, extracerebral vasculature; no impairment of cerebral blood flow follows its use. Other members of the triptan class include rizatriptan, zolmitriptan, and naratriptan. Vilazodone is an antidepressant with both partial 5-HT_{1A} receptor agonism and SERT inhibition.⁴⁴

Metoclopramide and tegaserod are prokinetic drugs that activate 5-HT₄ receptors to increase gut motility.¹⁴⁰ Because 5-HT₄ receptors are also found in the heart and urinary bladder detrusor muscle, 5-HT₄ agonists occasionally produce urinary incontinence and tachycardia.

Numerous indoles and phenylalkylamines, including ergot alkaloids, lysergic acid diethylamide (LSD), psilocybin, and mescaline, exhibit both agonistic and antagonistic properties at multiple 5-HT receptors. Their hallucinogenic/illusionogenic action is best explained by partial agonism at 5-HT_{2A} receptors.⁶⁴ Some substituted amphetamines (eg, methylenedioxymethamphetamine, XTC) directly stimulate 5-HT receptors.¹⁹⁸

Cocaine and indirect-acting sympathomimetics, especially amphetamines, cause 5-HT release as previously described.¹⁹⁸ Centrally, DA undergoes uptake into serotonergic neurons to displace 5-HT from the neuron. Ingestion of L-dopa or other xenobiotics that increase synaptic DA concentrations can cause 5-HT release.¹³²

Inhibitors of 5-HT reuptake include amphetamines, cocaine, various antidepressants, meperidine, tramadol, and dextromethorphan. Several antidepressants specifically inhibit 5-HT reuptake. Examples of selective 5-HT reuptake inhibitors (SSRIs) include fluoxetine, sertraline, paroxetine, and citalopram. The use of SSRIs sometimes produces

extrapyramidal side effects for reasons that remain unclear because of the numerous actions of 5-HT in the basal ganglia.⁷⁴ Two anticonvulsants, carbamazepine and lamotrigine, appear to inhibit 5-HT reuptake.¹⁹¹ Again, reserpine and tetrabenazine prevent 5-HT uptake into vesicles.

MAO-A accounts for most 5-HT degradation, and nonspecific MAOIs and MAO-A inhibitors (clorgyline, moclobemide) raise 5-HT concentrations and, through indirect action, probably cause 5-HT release. Some medications (eg, methylene blue, procarbazine, linezolid) have the undesired side effect of causing MAO inhibition, which occasionally produces serotonin toxicity when combined with other serotonergic drugs.

Serotonin Antagonists. Trazodone and nefazodone act mainly as antagonists at 5-HT₂ receptors, but are also weak reuptake inhibitors. Both undergo metabolism to m-chlorophenylpiperazine (mCPP), which activates most 5-HT receptors, but is especially active at 5-HT_{2C} receptors. Agomelatine is a novel antidepressant that antagonizes 5-HT_{2C} receptors and stimulates melatonin MT₁ and MT₂ receptors.⁵⁰ Ketanserin and ritanserin specifically antagonize 5-HT_{2C} receptors, while methysergide and cyproheptadine antagonize 5-HT₁ and 5-HT₂ receptors.¹⁴²

Mirtazapine exhibits complex actions, including antagonism of 5-HT_{2A}, 5-HT_{2C}, and 5-HT₃ receptors.⁶⁶ It also indirectly increases 5-HT_{1A} activity and enhances release of NE through antagonism of α_2 -adrenergic receptors. Mirtazapine demonstrates potent antagonism of histaminic and muscarinic receptors.⁶⁶

Most antipsychotics and tricyclic antidepressants antagonize 5-HT_{2A} and, to a lesser extent, 5-HT_{2C} receptors. In fact, investigators are interested in developing antipsychotics similar to risperidone that possess potent antagonistic properties at 5-HT₂ receptors, without accompanying potent DA receptor antagonism, in order to limit extrapyramidal side effects. These investigations have resulted in the introduction of olanzapine, sertindole, ziprasidone, zotepine, quetiapine, and amisulpride.¹³⁰

Ondansetron, granisetron, tropisetron, dolasetron, and alosetron antagonize 5-HT₃ receptors.¹⁴⁰ Their antiemetic action is thought to be explained by several mechanisms. Central antagonism at the CTZ lessens vomiting. Peripheral 5-HT₃ receptor antagonism in the gut prevents ACh release, decreasing gut motility. Finally, antagonism of vagal 5-HT₃ receptors decreases afferent stimulatory signals to the vomiting center in the brainstem. Metoclopramide antagonizes 5-HT₃ and D₂ receptors. Ondansetron and some experimental 5-HT₃ antagonists are being studied in the treatment of schizophrenia because of their ability to prevent DA release.

Tianeptine is an antidepressant with several pharmacologic effects, including enhancement of 5-HT reuptake, thus lowering synaptic 5-HT concentrations.¹⁶³

Serotonin Toxicity. Serotonin toxicity (formerly called serotonin syndrome) represents an iatrogenic and largely idiosyncratic condition that is most commonly caused by the combination of two or more proserotonergic xenobiotics, although it can happen following single 5-HT agonists in overdose or at therapeutic dosages.¹³⁶ Animal models indicate that serotonin toxicity can be prevented by the blockade of 5-HT_{1A} receptors and 5-HT_{2A} receptors.^{81,142,144} Serotonin toxicity is characterized by alterations in mentation and cognition, autonomic nervous system dysfunction, and neuromuscular abnormalities. Symptoms may include confusion, agitation, convulsions, coma, tachycardia, diaphoresis, hyperthermia, hypertension, shivering, myoclonus, tremor, hyperreflexia, and muscle rigidity (especially of legs).¹³⁶ Serotonin toxicity is often confused with neuroleptic malignant syndrome in its more severe presentation due to their similar manifestations. Serotonin toxicity usually responds to supportive care alone but may improve with 5-HT_{1A} and 5-HT_{2A} receptor antagonists such as cyproheptadine.^{22,136} Serotonin toxicity can be caused by xenobiotics, increasing CNS 5-HT neurotransmission (Table 14–7). In addition, xenobiotics that act to increase CNS DA concentrations, such as levodopa and bromocriptine, have potential to precipitate serotonin syndrome by indirectly causing 5-HT release (Chap. 75).

γ -Aminobutyric Acid

GABA is one of two main inhibitory neurotransmitters of the central nervous system (glycine is discussed later). Xenobiotics that enhance GABA activity are generally used as anticonvulsants, sedative-hypnotics, anxiolytics, and general anesthetics. Xenobiotics that antagonize GABA activity typically produce CNS excitation and convulsions. GABA is synthesized from glutamate, the brain's main excitatory neurotransmitter.

In general, GABA inhibition predominates in the brain. In the spinal cord, through monosynaptic and polysynaptic reflex pathways, GABA mediates a number of physiologically minor peripheral effects outside the CNS (eg, vasodilation, bladder relaxation). Spinal cord GABA is important in attenuating skeletal muscle reflex arcs.¹²²

Synthesis, Release, and Reuptake

Figure 14–9 illustrates GABA synthesis. Glutamate is converted to GABA via glutamic acid decarboxylase (GAD), which

requires pyridoxal phosphate (PLP) as a cofactor. Pyridoxal phosphate is synthesized from pyridoxine (vitamin B₆) by the enzyme pyridoxine kinase (PK).¹³³ VGAT, a vesicle-bound transporter, transports GABA into vesicles from where it is released through Ca²⁺-dependent exocytosis into the synapse.¹²² Reuptake of GABA from the synapse back into the presynaptic neurons is mediated by the Na⁺-dependent transporter, GAT-1, whereas uptake into glial cells and possibly postsynaptic neurons is mediated by GAT-2, GAT-3, and GAT-4. Evidence also suggests that GABA is released into the synapse from cytoplasm by reverse transport under some conditions. In glial cells, cytoplasmic GABA can undergo degradation by GABA-transaminase (GABA-T) to succinic semialdehyde (SSA), part of which then undergoes oxidation to succinate. GABA-T also requires PLP as a cofactor.¹⁵⁰ The transamination of GABA to SSA by GABA-T results in the conversion of α -ketoglutarate to glutamate, which then moves back into neurons to be used for resynthesis of GABA.

FIGURE 14–9. GABAergic neurotransmission. γ -aminobutyric acid (GABA) released from a presynaptic neuron (B) binds to postsynaptic GABA_A or GABA_B receptors to hyperpolarize and inhibit neuron D [5,6] or to presynaptic GABA_B heteroreceptors on neuron C [7] to inhibit neurotransmitter release by blocking Ca²⁺ influx (an excitatory glutamatergic neuron is shown as an example). Stimulation of GABA_B autoreceptors on neuron B [8] also reduces further release of GABA. Synaptic GABA undergoes reuptake into the presynaptic neuron by GAT-1, and uptake into glial cells and possibly postsynaptic neurons by GAT-2, GAT-3, and GAT-4 (GAT-2 is shown mediating uptake into glial cell A as an example.) Acute falls in pyridoxal phosphate (PLP) lead to impaired glutamic acid decarboxylase (GAD) activity and low GABA

concentrations. Although GABA-transaminase (GABA-T) also requires PLP, acute falls in PLP do not affect this enzyme as dramatically because of tight PLP binding to the GABA-T complex. Xenobiotics in Table 14–9 act to impair PLP formation by inhibiting pyridoxine kinase (PK) [1]; to increase GABA concentrations by either stimulating GAD [2] or inhibiting SSAD [3]; to inhibit GABA reuptake [4]; to stimulate or block GABA receptors [5–8]; to cause GABA release [9]; or to inhibit GABA-T [10]. Glutamic-oxaloacetic transaminase (GOT), GABA-T, and SSAD are mitochondrial enzymes. G = G protein; GAT = membrane GABA reuptake transporter; SA = succinic acid; SSA = succinic semialdehyde; SSAD = SSA dehydrogenase; VGAT = vesicle membrane GABA uptake transporter.

GABA Receptors

There are two main types of GABA receptors (Table 14–8). GABA_A receptors are Cl[−] channels that mediate inhibition by allowing Cl[−] to move into and hyperpolarize the neuron. Most GABA_A receptors are located postsynaptically and mediate fast or phasic inhibition. About 5% to 10% of GABA_A receptors are located outside the synapse and are responsible for slower tonic current that is present at resting membrane potential.^{73,115,141,175} Situated at various sites in relation to the GABA recognition site on the Cl[−] channel are sites for exogenous and endogenous modulators where numerous excitatory and depressant xenobiotics bind, and through which GABA_A receptor responsiveness is regulated under normal physiologic conditions (Fig. 14–10). The common denominator for modulation at the GABA_A complex is an increase or decrease in inward Cl[−] current.

TABLE 14–8. GABA Receptors and Their Characteristics		
	GABA _A	GABA _B
Receptor	Cl [−] Channel	G Protein-Coupled
Bicuculline antagonism	Yes	No
Baclofen agonism	No	Yes
Benzodiazepine agonism	Yes	No
Barbiturate agonism	Yes	No
Picrotoxin antagonism	Yes	No

GABA_A receptors exist as pentamers, composed of various subunits, and throughout the CNS there are regional variations in expressions of multiple subunit genes for GABA_A complexes. To date 19 subunits have been identified (α_1 to α_6 , β_1 - β_3 , γ_1 - γ_3 , δ , ϵ , θ , π , ρ_1 - ρ_3). GABA_A receptors are composed most commonly of two α subunits, two β subunits, and either a γ or δ subunit. Multiple isoforms of subunits exist, but within a single receptor, the isoforms of individual subunits appear to be identical. While the large numbers of isoforms and different combinations of subunits could theoretically produce more than 2000 different GABA_A Cl[−] channels, only a few dozen combinations exist naturally.^{42,141} The most common is $\alpha_1\beta_2\gamma_2$.^{11,186} Previously, GABA_C receptors were classified as a separate type of GABA receptor, but are now classified as GABA_A receptors comprising homo-oligomers and hetero-oligomers formed by ρ subunits (ρ_1 to ρ_3).

The second type of GABA receptor, GABA_B, is a G protein–coupled receptor found presynaptically, postsynaptically, and on extrasynaptic membranes. GABA_B receptors are heterodimers formed by two subunits, GABA_{B1} and GABA_{B2}. The GABA_{B1} subunit binds to GABA or other ligands such as baclofen, and the GABA_{B2} subunit couples the receptor with the effector G_{i/o} protein.¹³ GABA_B receptors are distributed both in the CNS and peripheral nervous system and mediate both presynaptic and postsynaptic inhibition.²¹ Presynaptic inhibition results from preventing Ca²⁺ influx so as to impair exocytosis of neurotransmitter vesicles, including those containing excitatory glutamate. Through presynaptic actions, GABA_B receptors serve not only as heteroreceptors for glutamatergic and other nerve terminals, but also as autoreceptors, where their activation in response to synaptic GABA provides feedback inhibition of further neurotransmitter release (Fig. 14–9). Postsynaptic inhibition is mediated by increasing K⁺ efflux through K⁺ channels, resulting in hyperpolarization of the membrane away from threshold. In addition to their effects on ion channels, GABA_B receptors, via the G_{i/o} protein, inhibit adenylate cyclase and, thus, the cAMP-protein kinase A pathway, which is necessary for the phosphorylation and upregulation of NMDA receptors.¹³

Xenobiotics

Table 14–9 provides examples of xenobiotics that affect GABAergic neurotransmission.

TABLE 14–9. Examples of Xenobiotics Affecting GABAergic Neurotransmission

<i>GABA Agonism</i>	<i>GABA Antagonism</i>
Stimulate GAD	Direct GABA _A antagonists
Valproate	Bicuculline
Direct GABA _A agonists	Cephalosporins
Muscimol	Ciprofloxacin
Progabide ^a	Imipenem
Indirect GABA _A agonists	Nalidixic acid
Barbiturates	Norfloxacin
Benzodiazepines	Ofloxacin
Chloral hydrate	Penicillins
Clomethiazole	Indirect GABA _A antagonists
Ethanol	Aztreonam
Etomidate	Clozapine
Felbamate	Cyclic antidepressants
Ivermectin	Flumazenil
Meprobamate	Lindane
Methaqualone	MAOIs
Propofol	Maprotiline
Steroids	Organic chlorine insecticides
Topiramate	Penicillins
Trichloroethanol	Pentylenetetrazol
Volatile anesthetics	Picrotoxin
Zaleplon	Inhibit GAD
Zolpidem	Cyanide
Zopiclone	Domoic acid
Direct GABA _B agonists	Hydrazines
Badofen	Isoniazid
GHB	4-Methoxypyridoxine ^d
Inhibit GABA-T	Direct GABA _B antagonists
Vigabatrin	Phaclofen ^b
Inhibit GABA reuptake	Saclofen ^b
Tiagabine	Inhibit PK
Valproate	Hydrazines ^c
	Isoniazid ^c

^aDirectly activates GABA_A and GABA_B receptors as well as being metabolized to GABA. ^bThought not to cross the blood–brain barrier in meaningful amounts. ^cMajor site of action is PK inhibition, though some direct GAD inhibition occurs. ^dFound in *Ginkgo biloba*.

GABA = γ -aminobutyric acid; GABA-T = GABA transaminase; GAD = glutamic acid decarboxylase; GHB = γ -hydroxybutyric acid; PK = pyridoxine kinase; MAOI = monoamine oxidase inhibitor.

Modulation of GABA Production and Degradation. Isoniazid (INH) and other hydrazines (eg, monomethylhydrazine from mushrooms) lower CNS GABA concentrations by several mechanisms. Most important, they compete with pyridoxine for binding to PK, impairing PLP production.¹³³ Pyridoxal phosphate binding to the GAD complex is easily reversible.¹⁵⁰ The acute decrease in PLP concentration is rapidly accompanied by impaired GABA synthesis and a decrease in GABA concentration. Lack of normal GABA inhibition produces seizures typical of hydrazine toxicity. Although PLP is also required for GABA degradation by GABA-T, acute decreases in PLP do not affect this enzyme nearly as much, because PLP is more tightly bound to the GABA-T complex and remains associated with the enzyme.¹⁵⁰ To a lesser extent, isoniazid binds to the GAD-PLP complex to prevent GABA formation.

Large ingestions of *Ginkgo biloba* seeds have resulted in recurrent seizures that may result from decreased GABA

concentrations. Ginkgo seeds contain 4-methoxypyridoxine, which acts as a competitive antagonist of pyridoxal phosphate, thereby inhibiting glutamate decarboxylase and impairing GABA synthesis.^{91,138}

Cyanide inhibits numerous enzymes besides cytochrome oxidase. Domoic acid (see Glutamate later) may also inhibit GAD.⁴³

In vitro studies demonstrate the ability of valproate to increase brain GABA concentrations, either by inhibition of succinic semialdehyde dehydrogenase or by activation of GAD.⁸⁸ Gabapentin may increase the rate of GABA synthesis in the brain by stimulating GAD, although the main mechanism of action of gabapentin is to bind to calcium channels.²⁰² Vigabatrin, an anticonvulsant, acts by irreversibly inhibiting GABA-T.¹⁹⁴

GABA_A Agonism. Figure 14–10 schematically illustrates the GABA_A receptor complex. In general, GABA_A agonists cause CNS depression, ranging from mild sedation and nystagmus to ataxia, stupor, and coma. Many indirect agonists that bind to the GABA_A complex have no activity in the absence of GABA. With some exceptions, their pharmacologic actions require the binding of GABA to its receptor and do not result from a direct effect on Cl[−] conductance exclusive of GABA binding. Many of these xenobiotics demonstrate additional actions that are not mediated through the GABA_A complex.

FIGURE 14–10. Representation of the GABA_A Cl[−] channel receptor complex. Benzodiazepines (BENZOs), barbiturates, picrotoxin, steroids, and GABA (γ-aminobutyric acid) clearly bind to different sites on the channel. Although separate circles represent different agents capable of binding to and of modulating Cl[−] influx through the GABA_A receptor complex, it is not always apparent where these xenobiotics bind on the channel. Chloral hydrate undergoes metabolism to trichloroethanol, which interacts with the GABA_A receptor complex. Zolpidem, zopiclone, and zaleplon are nonbenzodiazepines that bind to the benzodiazepine site. Given the structural similarity of glutethimide and methypylon to barbiturates, it is speculated that their action may be mediated at GABA_A receptors.

Direct GABA agonists. The main direct GABA agonist of toxicologic interest is muscimol, found in some poisonous mushrooms. Muscimol binds at the GABA binding site on the GABA_A complex to mimic the action of GABA.¹⁵² Ibotenic acid, a direct glutamate agonist found in the same mushrooms, is decarboxylated to muscimol just as glutamate is decarboxylated to GABA.

Indirect GABA agonists. Benzodiazepines bind to GABA_A complexes to increase the affinity of GABA for its receptor and to increase the frequency of Cl[−] channel opening in response to GABA binding.¹⁸⁵ The benzodiazepine binding site on the GABA_A receptor is located in a pocket between an α subunit and a γ₂ subunit.²¹¹ Benzodiazepines also inhibit adenosine uptake apart from GABA_A activity (see Adenosine later). The historical terms “benzodiazepine receptor” and “omega receptor” (for benzodiazepines) are being abandoned, and benzodiazepine-binding sites on subtypes of GABA_A receptors are categorized as high, intermediate, or low affinity benzodiazepine-binding sites, based on zolpidem binding.¹⁷⁴

It follows that various isoforms of GABA_A Cl[−] channels differ in their affinity for different benzodiazepines. GABA_A receptors containing γ₂ subunits are more sensitive to benzodiazepines than are GABA_A receptors containing γ₁ and γ₃ subunits. Sensitivity and response to benzodiazepine binding is also highly dependent on the specific α subunit composition of the GABA_A receptor. GABA_A receptors containing an α₄ or α₆ subunit are completely insensitive to and will not bind benzodiazepines, whereas GABA_A receptors containing α₁, α₂, α₃, or α₅ subunits are sensitive to benzodiazepine binding.

This has important implications in that the development of tolerance to ethanol confers cross-tolerance to benzodiazepines through a change in α subunits. In addition, specific subunits may mediate different effects of benzodiazepines. For example, sedating and amnestic effects are mediated through binding to α_1 subunits while anxiolytic effects appear to be mediated by binding to α_2 subunits.⁵⁷

Zolpidem, zaleplon, and zopiclone are non-benzodiazepines that act as agonists at the benzodiazepine binding site on the GABA_A receptor. They exhibit a high selectivity for the α_1 subunit and low selectivity for α_2 , α_3 , and α_5 subunits.^{189,211} This selective binding to α_1 subunits is thought to account for their relatively selective sedative properties at therapeutic doses, and lack of anxiolysis, as compared to benzodiazepines.

Barbiturates bind to the GABA_A complex to produce several effects.^{98,185} All barbiturates enhance the action of GABA by producing more Cl⁻ influx for a given amount of GABA binding by increasing the duration of Cl⁻ channel opening. Whereas phenobarbital does not change the affinity of GABA or benzodiazepines for their binding sites, depressant barbiturates, such as pentobarbital, do increase GABA and benzodiazepine binding site affinities for their ligands, further enhancing inward Cl⁻ currents. At high concentrations, at least some barbiturates directly open Cl⁻ channels to cause Cl⁻ influx.⁹⁸ Phenobarbital can directly open the Cl⁻ channel at antiepileptic concentrations. In addition, barbiturates possess other actions that depress all excitable membranes, including cardiac and smooth muscle.

The intravenous anesthetics propofol and etomidate enhance inward GABA_A Cl⁻ currents, and at high concentrations they directly open chloride channels in the absence of GABA.¹⁰ The respiratory depressant and immobilizing effects of etomidate and propofol are mediated by β_3 subunits, while the sedative effects are mediated through agonism at β_2 subunits.^{190,221} Volatile general anesthetics also directly activate GABA_A Cl⁻ channels.

Some of ethanol's action is mediated through binding to the GABA_A complex. The degree to which ethanol enhances the effect of GABA on Cl⁻ influx depends on the GABA_A receptor subunit composition. For example, receptors with an α_4 or α_6 subunit and a δ subunit respond to very low concentrations of ethanol.^{199,213}

Methaqualone produces at least part of its pharmacologic effect through indirect GABA_A activity. Little is known of the mechanisms of action of glutethimide and methyprylon. Their structural similarities to barbiturates suggest that they have activity at the GABA_A receptor. Trichloroethanol, a metabolite of chloral hydrate, and clomethiazole interact at the GABA_A complex in a manner similar to barbiturates, although it is not clear whether they are binding to an identical site on the Cl⁻ channel.²¹⁶ Ivermectin, an anthelmintic, activates GABA_A Cl⁻ channels by increasing GABA binding. Meprobamate displays barbituratelike action at the GABA_A receptor and, at high concentrations, is able to cause Cl⁻ influx in the absence of GABA.¹⁶⁹ High concentrations of felbamate also cause inward Cl⁻ currents in the presence of GABA, although this seems unimportant at therapeutic doses.¹⁶⁹ Part of the anticonvulsant action of topiramate may result from enhanced Cl⁻ influx through binding to GABA_A receptors.¹⁸⁰

Inhibition of GABA reuptake. Valproate and the anticonvulsants guvacine and tiagabine work, in part, by inhibiting GABA reuptake. Although valproate is structurally similar to GABA, its inhibition of the GABA transporter does not appear to be competitive.¹⁴⁸

GABA_A Antagonism. Direct GABA_A antagonists. Xenobiotics that act by any mechanism to decrease GABA_A activity can cause CNS excitation and convulsions by decreasing inhibitory inward Cl⁻ currents. Direct antagonists bind to the same site as GABA to prevent GABA binding, the prototype being the convulsant bicuculline. Various antibiotics interact with the GABA_A receptor to antagonize the action of GABA. In a dose-dependent manner, both imipenem and cephalosporins appear to directly antagonize GABA binding and can produce seizures at high doses or at therapeutic doses in susceptible individuals.²¹² Evidence suggests that penicillin may also directly antagonize GABA binding. Electrophysiologic and radioligand-binding studies indicate that norfloxacin, ciprofloxacin, ofloxacin, and enoxacin interact with the GABA binding site to prevent GABA binding.²¹² Theophylline and at least some NSAIDs markedly enhance GABA antagonism by some fluoroquinolones in vitro.²¹² Virol A, from *Cicuta virosa*, appears to directly antagonize binding of GABA to its receptor on the GABA_A complex.²⁰⁶

Indirect GABA_A antagonists. Penicillin is well known for producing convulsions at high doses (eg, >20 million units of penicillin per day with renal insufficiency), and both penicillin and aztreonam, a monobactam, appear to block the Cl⁻ channel to prevent GABA-mediated inward Cl⁻ currents.²¹²

Picrotoxin, from *Anamirta cocculus* (fish berries), and the experimental convulsant, pentylenetetrazol, bind to the picrotoxin site of the GABA_A receptor complex to inhibit the action of GABA. Excessive doses produce CNS excitation and convulsions. Some organochlorine insecticides (eg, lindane) also inhibit the action of GABA by binding to what appears to be the picrotoxin site and cause convulsions.¹¹⁷ Both α -thujone, the active component in wormwood oil, and

cicutoxin from the water hemlock noncompetitively antagonize GABA_A activity.^{78,207}

Flumazenil competitively antagonizes benzodiazepines, zolpidem, zaleplon, and zopiclone at their binding sites to reverse their pharmacologic effects.^{20,186} Paradoxically, large doses of flumazenil exhibit anticonvulsant activity in animals. This is explained, at least in part, by the ability of flumazenil to inhibit adenosine reuptake.^{159,195}

Cyclic antidepressants, including amoxapine and maprotiline, and at least two MAOIs (isocarboxazid and tranylcypromine) inhibit GABA-mediated Cl⁻ influx at GABA_A receptors.^{121,193} Their potency at inhibiting Cl⁻ influx correlates with the frequency of seizures that occur in patients taking therapeutic doses of these medications. Impaired GABA_A activity may contribute to or be primarily responsible for seizures that occur in patients who overdose on these xenobiotics. Their exact binding on the GABA_A receptor complex remains unknown, although some evidence suggests at least indirect activity at the picrotoxin-binding site.

Some subtypes of GABA_A receptors are susceptible to inhibition by zinc ions.¹⁸⁵ What role this plays in normal physiology or toxicology is not established.

GABA_A withdrawal. Acute withdrawal from all GABA_A direct and indirect agonists appears almost identical except for time course; the common denominator is impaired Cl⁻ influx. Withdrawal of all GABA_A agonists can cause tremor, hypertension, tachycardia, respiratory alkalosis, diaphoresis, agitation, hallucinations, and convulsions. When GABA_A receptors are chronically exposed to an agonist, changes in gene expression of receptor subunits occur, which lessens Cl⁻ influx in response to GABA or drug binding, producing tolerance. Importantly, withdrawal of the agonist produces yet further changes in subunit expression. For example, benzodiazepine-insensitive α_4 -subunit expression is increased following discontinuation of many GABA agonists, including benzodiazepines, zolpidem, zopiclone, zaleplon, neurosteroids, and ethanol. Expression of other subunits, including α_1 , γ_2 , β_2 , and β_1 also change in response to exposure and/or withdrawal of GABA_A agonists.⁵⁷ Alterations in GABA_A receptor subunit composition following chronic exposure to and withdrawal of an agonist can, therefore, affect the ability to successfully treat withdrawal symptoms. While any GABA_A receptor agonist may be used to treat withdrawal from another, some agents work better than others in different clinical settings. For example, patients experiencing severe alcohol withdrawal may have an increased proportion of GABA_A receptors containing benzodiazepine-insensitive α_4 subunits, and contain fewer GABA_A receptors with benzodiazepine-sensitive α_1 subunits.²⁷ Even extremely high doses of benzodiazepines in these patients may not effectively control severe alcohol withdrawal. A better treatment option in such a setting would be GABA_A agonists such as propofol or phenobarbital that either act on a different site on the GABA_A receptor or directly open the Cl⁻ channel.^{10,27} Phenytoin and carbamazepine do not stop GABA_A withdrawal seizures because their pharmacologic effects are independent of GABA_A agonism.

GABA_B agonists. The main GABA_B receptor agonist of toxicologic significance is baclofen, which is used for treatment of spasticity and some types of neuropathic pain. Coma, hypothermia, hypotension, bradydysrhythmias, and seizures characterize its toxicity. The convulsions that occur in patients with baclofen overdose are proposed to result from disinhibition (inhibition of inhibitory neurons). Carbamazepine's activation of GABA_B receptors has been demonstrated, although this is not thought to explain most of its anticonvulsant action. Some of the actions of γ -hydroxybutyrate following pharmacologic doses may be mediated through activation of GABA_B receptors.

GABA_B withdrawal. Baclofen withdrawal is similar clinically to GABA_A withdrawal. Hallucinations, agitation, tremor, increased sympathetic activity, and convulsions are the main characteristics of baclofen withdrawal. Withdrawal from chronic intrathecal baclofen administration may also be accompanied by large swings in autonomic tone (hypotension, hypertension, tachycardia, bradycardia) and transient cardiomyopathy and shock. Reinstitution of oral baclofen therapy following oral withdrawal, or intrathecal baclofen following intrathecal withdrawal is the treatment of choice when possible.¹²²

γ -HYDROXYBUTYRATE

γ -Hydroxybutyrate (GHB; γ -hydroxybutyric acid) exists endogenously, but toxicologic interest stems from its use in supraphysiologic doses as a drug of abuse and as a treatment for narcolepsy.^{17,55,107} GHB is rapidly absorbed and freely crosses the blood-brain barrier. Toxicity resulting from ingestion of GHB is explained by GHB receptor and GABA_B receptor activation, and comprises agitation, tremor, rapid onset of coma, vomiting, bradycardia, hypotension, hypotonia, and apnea that usually resolve within several hours. Although seizures are noted in experimental animals, it is debated whether GHB causes true convulsive activity in human beings. Human experiments with "therapeutic" doses of GHB have not found EEG changes consistent with seizure activity.¹⁰⁷ Interestingly, patients with the rare inborn error of metabolism, succinic semialdehyde dehydrogenase (SSAD) deficiency, have elevated GHB concentrations and tend to experience

seizures.⁶⁵ Valproate elevates endogenous GHB concentrations by inhibiting SSAD.

Controversy exists as to whether GHB should be considered a neurotransmitter or simply a neuromodulator because it is unclear whether GHB is concentrated within vesicles for synaptic release. There is evidence demonstrating a sodium-dependent reuptake transporter for GHB.

GHB receptors are heterogeneously distributed throughout the brain, with highest concentrations in the hippocampus, cortex, limbic areas, and thalamus, as well as in regions innervated by dopaminergic terminals and dopaminergic nuclei. GHB receptors exist on neurons, mainly at the synaptic level, but are absent from glial or peripheral cells. At least two general GHB receptors have been described thus far, based on binding affinity for GHB and other ligands.

Several proposed pathways for endogenous GHB formation exist (Fig. 14–11).¹⁷ Evidence exists for GHB's metabolism back to GABA, although this appears minimal at physiologic GHB concentrations.⁵⁵ However, effects resulting from pharmacologic doses of GHB may result, in part, from secondary GABA formation.

FIGURE 14–11. Potential pathways of γ -hydroxybutyrate (GHB) synthesis and degradation. GABA = γ -aminobutyric acid; GBL = γ -butyrolactone; SSA = succinic semialdehyde; [1] = glutamic acid decarboxylase; [2] = GABA-transaminase; [3] = succinic semialdehyde dehydrogenase; [4] = specific succinic semialdehyde reductase and/or nicotinamide adenine dinucleotide phosphate (NADPH)-dependent aldehyde reductase 2; [5] = mitochondrial β oxidation; [6] = alcohol dehydrogenase and aldehyde dehydrogenase; [7] = GHB dehydrogenase; [8] = γ -lactonase.

Although normal endogenous GHB concentrations are probably not high enough to activate GABA_B receptors, such receptor activation may occur with exogenous administration of GHB. Furthermore, there appears to be functional interplay between GHB and GABA_B receptors.¹⁷

Specific interactions between GHB and DA are complex and not fully delineated. Treatment with GHB appears to inhibit DA release, probably via stimulation of GABA_B receptors.²¹⁷ GHB also affects the firing rates of dopaminergic neurons, DA synthesis, and levels of DA and its major metabolites. GHB is thought to affect sleep cycles, temperature regulation, cerebral glucose metabolism and blood flow, memory, and emotional control, and it may be neuroprotective.

Although GHB can suppress alcohol withdrawal, it is also addictive, and both tolerance and a withdrawal syndrome are described. Withdrawal is characterized, in part, by insomnia, cramps, paranoia, hallucinations, tremor, and anxiety.

GLYCINE

Glycine acts as an inhibitory neurotransmitter in the spinal cord and lower brainstem. In the CNS, serine is converted to glycine by serine hydroxymethyltransferase (SHMT). Some sources of serine include degradation of proteins and phospholipids through dietary intake and formation from 3-phosphoglycerate in a three-step biosynthetic pathway.

Release and Reuptake

Glycine is transported into storage vesicles by VGAT (also known as VIAAT) and undergoes Ca^{2+} -dependent exocytosis upon neuronal depolarization (Fig. 14–12). Glycine is removed from the synapse through reuptake by a Na^{+} -dependent transporter into presynaptic neurons and into glial cells. Two glycine membrane transporters have been cloned and share homology with GABA uptake transporters. GLYT-1 is found both in astrocytes and neurons, whereas GLYT-2 is localized on axons and terminal boutons of neurons that contain vesicular glycine. Although both transporters are associated with glycinergic neurons in the brainstem and spinal cord, GLYT-1 is also found in the forebrain in regions devoid of

glycinergic neurotransmission. At the latter location, GLYT-1 may regulate extracellular glycine that is available for NMDA receptor activation, and GLYT-1 inhibitors could then enhance NMDA responses (Table 14–11). Glycine transporters can also function in reverse, moving glycine out of the cell.⁵

FIGURE 14–12. Inhibitory glycinergic neurotransmission. Glycine is concentrated within vesicles by uptake via VGAT, the vesicle membrane transporter. Signals from the afferent limb of a reflex arc (top right) cause the release of an excitatory neurotransmitter (ENT) that crosses the synapse to bind to a neuron in the efferent limb of the reflex arc [1]. To prevent excessive neuronal firing and motor activity, glycine (Gly) released from a glycinergic inhibitory neuron [2] binds to glycine Cl^- channel receptors [3] and causes inhibition by hyperpolarization through Cl^- influx. Synaptic glycine is transported back into the neuron by at least two subtypes of membrane glycine transporters, GLYT-1 and GLYT-2 [4]. Strychnine binds to the glycinergic Cl^- channel to decrease the binding of glycine, which prevents Cl^- influx. Although strychnine is shown to bind to a separate site from glycine, there is evidence that these sites may overlap. GLYT = glycine reuptake transporter.

Glycine Receptors

The glycine receptor is a Cl^- channel that shares significant amino acid homology with the GABA_A Cl^- channel. It is well established that both GABA and glycine are excitatory in the embryonic central nervous system prior to becoming the main inhibitory neurotransmitters of the mature CNS.^{46,103,162} Glycine receptors are pentameric proteins made up of α and β subunits. Three isoforms of the α subunit (two of which exist after the neonatal period) and one isoform of the β subunit are described.¹³¹ An anchoring protein, gephyrin, binds to the β subunit and allows for clustering of glycine receptors at postsynaptic membranes. Like GABA receptors, glycine receptors may also be found outside the synapse, where their

function is an area of current research.^{103,215} Glycine receptor activation causes an inward Cl^- current that hyperpolarizes the membrane. Glycine binding is also important for functioning of the NMDA receptor as discussed later.

Xenobiotics

Table 14–10 provides examples of xenobiotics that affect inhibitory glycine Cl^- channels. The amino acids β -alanine, taurine, and serine can activate glycinergic Cl^- channels. Both ethanol and propofol potentiate glycine-mediated inward Cl^- currents, just as they do at GABA_A Cl^- channels.^{125,131} Volatile halogenated anesthetics, ivermectin, δ -9-tetrahydrocannabinol, and chlormethiazole also potentiate glycinergic transmission.²¹⁵ Clozapine inhibits glycine reuptake.⁸²

TABLE 14–10. Examples of Xenobiotics Affecting Inhibitory Glycine Chloride Channels

<i>Glycine Agonists</i>	<i>Glycine Antagonists</i>
β -Alanine	Glycine reuptake inhibitor
Ethanol	Atropine
Halogenated anesthetics (volatile)	Clozapine
Ivermectin	Ginkgolide B
Propofol	Picrotoxin
Serine	Strychnine

Strychnine is the main xenobiotic affecting glycinergic transmission. Strychnine binds to the α subunit of the glycine receptor to prevent the action of glycine on Cl^- influx,⁴ at least in part by decreasing the binding of glycine to its receptors. This physiologic antagonism of glycine produces increased muscle tone, rigidity, opisthotonus, trismus, rhabdomyolysis, and death from respiratory failure. Given the similarity in Cl^- channels, it is not surprising that strychnine binds to the GABA_A complex in vitro. However, the affinity of strychnine for this complex is less than that for glycine receptors, and most of its toxicologic action is a result of physiologic antagonism of glycine-induced inhibition.

Picrotoxin binds to the glycine receptor to impair Cl^- influx.¹¹⁸ Evidence exists for a direct antagonistic effect of picrotoxin at the glycine binding site(s), in contrast to GABA_A Cl^- channels, where it acts at a site separate from where GABA binds. Ginkgolide B appears to inhibit the glycine receptor by directly blocking the Cl^- channel.²¹⁵ Tetanus toxin produces rigidity and trismus by preventing glycine release from neuronal terminals in the spinal cord and brainstem.

GLUTAMATE

Glutamate is the main excitatory neurotransmitter in the CNS and the immediate precursor to the main inhibitory neurotransmitter, GABA. Balance between glutamate neuronal stimulation and GABA neuronal inhibition is essential to maintain normal CNS function.^{82,90} Glutamate is essential for memory, learning, perception, locomotion, and neuropsychiatric well-being.^{14,36,46} A number of psychiatric and neurologic disorders are associated with altered glutamatergic function, including schizophrenia, depression, anxiety, posttraumatic stress disorder, addiction and withdrawal, autism, epilepsy, Alzheimer disease, and amyotrophic lateral sclerosis (ALS).^{36,46,62,82,119} Although glutamate receptor stimulation is essential for normal brain activity, excessive endogenous or exogenous stimulation plays a significant role in mediating neuronal damage in acute, progressive, and chronic psychiatric and neurologic diseases, including damage from trauma, ischemia, hypoglycemia, and status epilepticus.^{14,126} A rise in synaptic glutamate concentrations after neurological insult that induces further damage and apoptosis is termed glutamate-related excitotoxicity.^{46,119} Conversely, glutamate antagonists demonstrate neuroprotective properties and anticonvulsant activity in animal models of CNS injury. Unfortunately, clinical trials with currently available glutamate antagonists for treatment of patients with ischemic stroke and traumatic brain injury have proved disappointing.⁴⁶

Synthesis, Release, and Reuptake

Glutamate does not cross the blood–brain barrier and must be synthesized from products of glucose metabolism or other precursors within the CNS. Glutamate primarily is synthesized from glutamine by the enzyme glutaminase located within the mitochondrial compartment.⁵⁸ Glutamate is stored within vesicles and then released into the synapse by Ca^{2+} -dependent exocytosis. Synaptic glutamate that is taken up by glial cells undergoes conversion back to glutamine by the enzyme glutamine synthase. Glial cells then release glutamine, which is taken up by neurons before conversion back to glutamate and subsequent transport into vesicles (Fig. 14–13). Reverse transport of glutamate from the cytoplasm into the synapse by

the membrane transporter may occur under some circumstances.⁹ There are five different cell surface excitatory amino acid transporters (EAAT) that differ in their predominant CNS locations.

FIGURE 14–13. Glutamatergic neurotransmission. Glutamic oxaloacetic transaminase (GOT) converts α -ketoglutarate to glutamate in mitochondria. Glutamate also forms from glutamine via mitochondrial glutaminase. Glutamate is transported into vesicles [6] by VGLUT1 (or possibly other subtypes) for exocytotic release into the synapse. Synaptic glutamate activates four main types of receptors. AMPA [2], kainate [3], and NMDA [4] receptors are cation channels. Membrane depolarization in response to their activation causes neuronal excitation through cation influx. Metabotropic receptors (mGluR) [1,8] are coupled to G proteins and are expressed on pre- and postsynaptic membranes. In addition, some mGluRs reside outside of the synapse. Postsynaptic mGluR excitation in this example [1] results from preventing K⁺ efflux, but other mechanisms of excitation exist. Presynaptic mGluRs act to inhibit [8] glutamate (and other neurotransmitter) release through modulating intracellular Ca²⁺ concentrations, as do presynaptic GABA_B receptors in response to GABA binding [9].

Figure 14–14 provides a more detailed illustration of the NMDA receptor. Excessive influx of Ca²⁺ through NMDA receptors (and through some AMPA and kainate receptors) causes neuronal damage and cell death. A Mg²⁺ ion normally blocks the NMDA receptor channel to prevent Ca²⁺ influx despite glutamate binding. However, depolarization of the neuronal membrane by cation influx resulting from activation of any of the other receptor types causes Mg²⁺ to dissociate from the NMDA receptor and to allow potentially damaging inward Ca²⁺ currents in response to glutamate binding.

Glutamate undergoes reuptake by neurons and glial cells by various subtypes of EAAT, the membrane bound glutamate transporter [5]. In glial cells, glutamate is converted to glutamine by glutamine synthase, and glutamine is transported out of glial cells by the system N amino acid transporter (SN3). Glutamine then moves back into neurons through another amino acid transporter (SNAT1) [7] where it undergoes conversion back to glutamate. Various xenobiotics in [Table 14–11](#) affect glutamatergic neurotransmission, in part, by stimulating or blocking the various glutamate receptors [1–4,8] or by preventing glutamate reuptake [5]. G = G protein.

Glutamate Receptors

Once glutamate undergoes release into the synaptic cleft, it can bind to one of three ionotropic receptors or eight metabotropic receptors. The three ionotropic glutamate receptors are cation channels and named according to their affinity for specific agonists: kainate, AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazole propionate), and NMDA (N-methyl-D-aspartate). All comprise four subunits and are responsible for fast excitatory glutamatergic activity.^{35,46,56,90,93,129,161} The eight metabotropic receptors are linked to G proteins and produce actions that are slower, more diverse, and longer-lasting than those of ionotropic receptors.^{56,93} Presynaptic terminal glutamate receptors modulate the release of various neurotransmitters, including glutamate, while postsynaptic glutamate receptors are usually excitatory, although some inhibitory actions are demonstrated. ([Fig. 14–13](#)).^{129,161} A single neuron may express numerous types of glutamate receptors. Every type of glutamate receptor has been identified on both presynaptic and postsynaptic membranes, but many are not active under normal physiologic conditions. This complexity offers protection against the devastating effects of uncontrolled excitatory neurotransmission.

Ionotropic Glutamate Receptors. Ionotropic cationic glutamate receptors share structural similarity, especially kainate and AMPA receptors. These receptors are homomeric or heteromeric tetramers with a central ion channel pore. The inward current carried through most ionotropic glutamate receptors results from Na^+ and/or Ca^{2+} influx.^{90,129,203}

AMPA receptors are hetero- and homotetramers comprising GluA1–4 subunits that are the most common ionotropic glutamate receptors found in the brain and are responsible for most glutamatergic excitation, mainly through Na^+ influx under normal conditions.^{30,90,145,203} Post-transcriptional modification or RNA editing of AMPA receptor subunits alters ion permeability and function. In adults, nearly all GluA2 subunits are edited, resulting in maintenance of Na^+ permeability, but loss of Ca^{2+} permeability. In contrast, some unedited GluA2 subunits demonstrate Ca^{2+} and Zn^{2+} permeability.^{46,90,129,145,158} These AMPA receptors permeable to Ca^{2+} are more prevalent in many neurological diseases where they may contribute to excitotoxicity.^{90,129}

Kainate receptors are named for their affinity for kainate, found in red algae. These receptors comprise GluK1-5 subunits joined in homomeric and heteromeric tetramers.^{85,90,171} Activation allows Na^+ influx, and lesser K^+ efflux, resulting in neuronal depolarization. RNA editing of GluK1 and GluK2 subunits abolishes Ca^{2+} permeability while maintaining Na^+ conductance, but some subunits remain unedited and permeable to Ca^{2+} .^{30,158} Recent studies indicate that some kainate receptors may also signal through G-proteins in a yet-to-be understood mechanism.³⁷

NMDA receptors are heteromeric tetramers of subunits that may include GluN1, GluN2A-2D, and GluN3A-3B (7 isoforms), but most commonly comprise two GluN1 and two GluN2 subunits.^{14,46,90,92,203} NMDA receptors reside near AMPA receptors, forming a functional synaptic unit at virtually all central synapses.²⁰³ NMDA receptor activation allows for Ca^{2+} and Na^+ influx (and some K^+ efflux), resulting in neuronal depolarization and excitation ([Fig. 14–14](#)). The NMDA ion channel is normally blocked by Mg^{2+} in a voltage-dependent manner, preventing Ca^{2+} influx despite glutamate binding ([Fig. 14–14](#)).^{82,92} For Ca^{2+} to flow through the channels, three conditions must be met: (1) the neuronal membrane must be depolarized by at least 20 to 30 mV through some other mechanism (eg, activation of another type of glutamate receptor) so that Mg^{2+} will leave the channel, (2) two molecules of glutamate must bind to the receptor, and (3) two molecules of glycine must bind to their binding sites on the receptor.^{46,56,92,119} The amino acid D-serine may substitute for glycine.^{14,90} Thus, the NMDA receptor is both a ligand-gated and voltage-gated ion channel ([Fig. 14–14](#)). Direct Ca^{2+} influx through both NMDA and Ca^{2+} -selective AMPA channel receptors contributes to excitotoxicity. Excessive stimulation of NMDA and AMPA receptors by glutamate released during times of ischemia, trauma, hypoglycemia, or convulsions triggers damaging rises in intracellular Ca^{2+} concentrations, activation of numerous enzymes, and free radical formation, all of which incite cell death.¹²⁶ Antagonists of NMDA Ca^{2+} channels demonstrate anticonvulsant and neuroprotective activity. Zinc is packaged into synaptic vesicles in axons and is co-released with glutamate into the synaptic cleft during neuronal activity where it acts as an endogenous modulator of NMDA receptors.²⁰³

FIGURE 14–14. Representation of the NMDA glutamate receptor. The NMDA receptor is a voltage-gated and ligand-gated Ca^{2+} channel. Glutamate binds to its receptor on the channel [2] to open the Ca^{2+} channel and to allow Ca^{2+} and Na^{+} influx and lesser amounts of K^{+} efflux. Mg^{2+} normally blocks the Ca^{2+} channel, preventing cation influx in response to glutamate binding. Mg^{2+} leaves the channel when the membrane is depolarized by 20–30 mV. Glycine must also bind to its site on the NMDA receptor complex for successful glutamate agonism. Polyamines bind on the extracellular surface of the receptor [5]. Zn^{2+} binds [4] to inhibit Ca^{2+} influx. The phencyclidine (PCP) binding site [3] lies within the channel. Xenobiotics in Table 14–11 may antagonize glycine binding [1]; block the Ca^{2+} channel by binding to the PCP binding site [3]; bind to the polyamine binding site [5]; or directly stimulate the glutamate-binding site [2].

Metabotropic Glutamate Receptors. Metabotropic glutamate receptors (mGlu) are linked to various G proteins on post- and presynaptic membranes (Fig. 14–13). Eight different receptors (mGlu1–8) have been isolated. In contrast to ionotropic glutamate receptors, mGlu may excite or inhibit at postsynaptic membranes, and appear mainly to inhibit at presynaptic locations, regulating synaptic transmission and neuronal excitability.

Metabotropic glutamate receptors are commonly subdivided into three main groups based on their sequence homology, intracellular signaling mechanisms and response to specific experimental agonists.^{182,200} As a general rule, group I receptors (mGlu1 [a,b,c,d] and mGlu5 [a,b]) reside postsynaptically; activation produces excitation through blockade of K^{+} efflux or by activating phospholipase C, producing rises in intracellular Ca^{2+} , resulting in cell depolarization.^{36,56,182,200} The mGlu5 receptors are physically coupled to NMDA receptors by scaffolding proteins and are functionally coupled to NMDA receptors by protein kinase C.^{36,56,182} In animal experiments, agonists of group I receptors produce convulsions, while antagonists display anticonvulsant action.^{56,114,119,182} Group II (mGlu2, mGlu3) and Group III (mGlu4, mGlu6, mGlu7, mGlu8) metabotropic receptors most commonly serve as presynaptic autoreceptors and heteroreceptors and, when activated, inhibit adenylate cyclase activity.^{36,56,161,172,200} This, in turn, prevents Ca^{2+} influx and inhibits release of neurotransmitters, including glutamate, GABA, DA, and adenosine. Group II presynaptic autoreceptors may play an important role in decreasing further glutamate release during pathologic conditions, when extracellular concentrations of glutamate exceed normal physiologic levels. They are positioned outside the synaptic active zone and, therefore, only become activated when glutamate spills out of the synapse.¹⁶¹ The mGlu7 receptor is positioned within the active zone of the synapse, but has a low affinity for glutamate, allowing for a continuous but mild inhibitory effect on glutamate release.^{161,200} Agonists of Groups II and III metabotropic receptors produce anticonvulsant effects in animals.¹²⁴

The glutamate binding pocket is so well conserved among the mGlu receptors that it has been difficult to find subtype selective agonists or competitive antagonists. Therefore, drug development is now focused on negative and positive allosteric modulators (NAMs and PAMs).¹⁷² Allosteric modulators bind mGlu receptors at a site distinct from the glutamate binding site and alter the functioning of the receptor in the presence of glutamate. The NAMs block activation of G proteins by the mGlu receptor, while PAMs facilitate the action of direct receptor agonists. Allosteric modulators are being developed to treat hyperlocomotion, psychosis, and schizophrenia.^{36,56,172}

Xenobiotics

Table 14–11 provides examples of xenobiotics that affect glutamatergic neurotransmission.

TABLE 14–11. Examples of Xenobiotics Affecting Glutamatergic Neurotransmission

Glutamate agonism

Direct glutamate receptor agonists

BMAA

Domoic acid

Homoquinolinic acid
Ibotenic acid
ODAP (formerly BOAA)
Quisqualate
Willardine
AMPA receptor modulators
Aniracetam
BMAA
Cyclothiazide
Dysiherbaine
Minocycline
ODAP (formerly BOAA)
Kainate receptor modulators
Concanavalin A
Domoic acid
Dysiherbaine
Neodysiherbaine A
NMDA receptor modulators
Nitric oxide
Glycine NMDA receptor agonists
Alanine
d-Cycloserine
Kynurenic acid
Milacemide
Serine
Glutamate reuptake inhibitor
Clozapine
Nitropropionic acid
Glutamate antagonism
Prevent glutamate release
Diazoxide
Felbamate

Lamotrigine
Nimodipine
Riluzole
Sulfasalazine
Increase glutamate reuptake
Ceftriaxone
Lithium
Riluzole
AMPA receptor antagonists
Quinoxalinediones
Talampanel
Topiramate
NMDA receptor antagonists
Amantadine
Buprenorphine
Conatoxins
Dextrophan
Dimebon
Dizocilpine (MK801)
Ethanola
Ketamine
Memantine
Meperidine
Methadone
Methoxetamine
Neramexane
Orphenadrine
Pentamidine
Phencyclidine
Promethazine
Remacemide
Selfotel

Tramadol

NMDA glycine antagonists

Felbamate

Kynurenic acid

Meprobamate

Xenon

Kainate receptor antagonists

Quinoxalinediones

Topiramate

Metabotropic negative allosteric modulator

Fenobam

Polyamine antagonists

Aptiganel

Arecaine

Argiotoxin

Diethylenetriamine

Eliprodil

Ifenprodil

^aEthanol is a noncompetitive antagonists at some NMDA receptors.

BMAA = α -amino- β -methylaminopropionic acid; ODAP = L- β -N-oxalyl- α , β -diaminopropionic acid; BOAA = β -N-oxalylamino-L-alanine; NMDA = N-methyl-D-aspartate.

Glutamate Agonism. Domoic acid produces amnesic shellfish poisoning, partly characterized by confusion, agitation, convulsions, memory disturbance, neuronal damage, and death.⁷⁵ The structural similarity between domoic acid and glutamate is thought to explain excessive activation of AMPA and kainate receptors with secondary NMDA receptor activation and resultant neuronal damage.⁷⁷ Domoic acid toxicity in birds is thought to have explained their attack on the city of Capitola, CA in 1961, and may have partly inspired Hitchcock's creation of the movie, *The Birds*.³⁹

Investigators hypothesize that other naturally occurring glutamate receptor agonists produce additional neurologic diseases. The neurogenic form of lathyrism results from using chickling peas (*Lathyrus sativus*) as a food staple. Neurolathyrism was common in German concentration and prisoner of war camps during World War II and still occurs in some parts of the world. Chickling peas contain L- β -N-oxalyl- α , β -diaminopropionic acid (ODAP), previously known as β -N-oxalylamino-L-alanine (BOAA), an agonist of AMPA receptors.^{99,209} Influx of Ca^{2+} likely contributes to motor neuron cell death in neurolathyrism.²⁰⁹

Endemic ALS–Parkinson disease in Guam has been hypothesized to be from chronic toxicity from β -methylamino-L-alanine (BMAA), which is formed by cyanobacteria symbiotically residing within the roots of Cycads (*Cycas micronesica*). BMAA and its carbamate are structurally similar to glutamate,²³ and experiments demonstrate that prolonged exposure to BMAA produces Ca^{2+} influx into substantia nigra pars compacta dopaminergic neurons and excitotoxic effects through activation of metabotropic glutamate receptors (mGlu1), and to a lesser extent, AMPA receptors.⁴⁰ Consumption of raw Cycas seeds, of flour made from Cycas, or of animals that have eaten Cycas, results in an accumulation of protein-bound BMAA within brain tissues of humans that can be demonstrated at autopsy. However, autopsies of patients throughout the world with ALS, Alzheimer disease, and Parkinson disease, in absence of Cycas exposure, also demonstrate elevated brain BMAA concentrations, and cyanobacteria that produce BMAA are ubiquitous, making interpretation of

BMAA's role in producing ALS–Parkinson disease difficult.

Ibotenic acid, from poisonous mushrooms, activates NMDA and some metabotropic glutamate receptors. It undergoes decarboxylation to muscimol, a direct agonist of GABA_A receptors. Glufosinate is a tripeptide and glutamate analogue isolated from *Streptomyces* and utilized in herbicides. Glufosinate produces excitotoxicity in humans, manifesting as drowsiness, amnesia, confusion, coma, seizures or death, through activation of NMDA receptors.¹²³

There is in vitro evidence that ketamine causes glutamate release from neuronal terminals. Ketamine and methoxetamine may directly activate AMPA glutamate receptors, and this effect may explain their potential antidepressant action.^{38,110,119,129}

Because noncompetitive NMDA receptor antagonism reproduces many signs and symptoms of schizophrenia and autism, investigators are directing efforts at increasing activity at NMDA channels in an effort to treat these diseases,^{184,220} and potentiating activity at the glycine-binding site may enhance NMDA receptor function. After crossing the blood–brain barrier, milacemide undergoes conversion to glycine, which is required for NMDA receptor activation.¹⁸⁴ D-Cycloserine also crosses the blood–brain barrier to stimulate glycine receptors on NMDA calcium channels.⁹² Sarcosine (N-methylglycine) is a glycine transporter-1 inhibitor, raising synaptic glycine concentrations near NMDA receptors.⁸³

N-acetylcysteine (NAC) modulates glutamate through the astrocytic antiporter cysteine/glutamate, resulting in stimulation of metabotropic glutamate receptors and activation of NMDA receptors. Also, NAC likely potentiates AMPA receptors. Some have suggested NAC as a treatment for Parkinson disease and for depressive symptoms of bipolar disease.¹¹⁰

Aniracetam inhibits deactivation of AMPA receptors and has been advocated as a nootropic agent for patients with dementia.^{90,97} Minocycline and cyclothiazide attenuate receptor desensitization and demonstrate neuroprotective effects.^{84,90,129}

Glutamate Antagonism. Prevention of glutamate release. Riluzole is used to treat ALS and is being considered for neuroprotection in Parkinson disease and for treatment of depression. Overall, riluzole increases glutamine/glutamate ratios. It indirectly prevents release of glutamate by inhibiting voltage-dependent Na⁺ channels and facilitates uptake of glutamate from the synapse by stimulating EAAT activity.^{46,119,129} Riluzole also enhances AMPA trafficking, enhances membrane insertion of AMPA receptors, and promotes neurogenesis through stimulation of growth factors.^{46,92,119} Lamotrigine diminishes glutamate release through blockade of voltage-gated Na⁺ channels and increases AMPA receptor activity.¹¹⁹ Felbamate antagonizes NMDA receptors and prevents glutamate release.⁴⁶ Gabapentin and pregabalin inhibit presynaptic Ca²⁺ channels to lessen glutamate release.

AMPA receptor antagonists. Talampanel, a noncompetitive antagonist, has been investigated in the treatment of ALS and has anticonvulsant properties.¹²⁹ Some wasp and spider venoms contain AMPA receptor antagonists.¹²⁹

NMDA receptor antagonists. Phencyclidine, ketamine, and metho-xetamine act as noncompetitive antagonists by binding within the ion channel (PCP binding site) to block Ca²⁺ influx following glutamate binding (Fig. 14–14).^{82,92}

Dextromethorphan and its first-pass metabolite, dextrorphan, exhibit anticonvulsant activity and psychoactive effects in animals. Most of the actions of dextromethorphan are due to its metabolite, dextrorphan, which antagonizes the actions of glutamate at NMDA receptors by binding to the PCP binding site. Both compounds directly block N- and L-subtype voltage-dependent Ca²⁺ channels.^{92,168}

Tramadol displays multiple mechanisms of action as an analgesic, including a weak affinity for opioid receptors, inhibition of monoamine reuptake, and inhibition of NMDA glutamatergic activity at clinically relevant concentrations by an unknown mechanism.⁷⁰ Methadone, meperidine, and buprenorphine are opioid analgesics that antagonize NMDA receptors at therapeutic doses, and this mechanism of action may contribute to their analgesic effect.⁴⁵

Dizocilpine (MK-801) antagonizes NMDA receptors by binding to the PCP binding site in the NMDA Ca²⁺ channel, producing adverse effects, similar to phencyclidine.⁴⁹ Amantadine, memantine, and orphenadrine act as low-affinity antagonists at the PCP site, but are not associated with psychotomimetic adverse effects from such action.⁹² Memantine is a low-affinity NMDA receptor antagonist, which is approved for the treatment of Alzheimer disease, but has also recently been utilized for the treatment of other neurological and psychiatric disorders.^{14,46,119,201,203} Ifenprodil is a GluN2B-subunit-selective antagonist of NMDA receptors that has been advocated for neuroprotection in stroke patients.¹⁴⁹ Pentamidine antagonizes glutamate binding at NMDA channels.⁴⁹

Ethanol noncompetitively antagonizes NMDA receptors, resulting in upregulation of this glutamatergic system.²⁰³ Alcohol-tolerant individuals show marked reductions to subjective intoxicating effects of ketamine.¹¹⁹ In some animal models of ethanol withdrawal seizures, NMDA receptor antagonists demonstrate better anticonvulsant action than GABA_A agonists.

Glycine antagonism. Felbamate's anticonvulsant activity may result, in part, from antagonism of glycine at NMDA

receptors.^{157,218} Kynurenic acid, a metabolite of L-tryptophan, prevents NMDA activation through glycine antagonism. Meprobamate also antagonizes NMDA glutamate receptors by a yet-to-be-determined mechanism.¹⁵⁷ However, given the structural similarity to felbamate, meprobamate may antagonize the action of glycine.

Polyamine Antagonism. Ifenprodil and eliprodil antagonize the action of glutamate at NMDA channels by preventing polyamine binding.⁶⁸

ADENOSINE

Adenosine is an important modulator of brain activity and body physiology. Adenosine receptors are vastly distributed throughout the body, which emphasizes the pivotal role that adenosine plays in neurotransmission and metabolic activity.

The overall action of adenosine is to lessen oxygen requirements and to increase oxygen and substrate delivery.⁵⁹

Adenosine can be found in small concentrations in most extracellular fluids as a consequence of ATP metabolism. This is in contrast to classical neurotransmitters, which are secreted in discrete quanta upon stimulation of presynaptic neurons. In the brain, adenosine primarily limits glutamate and ACh release, thereby preventing excessive postsynaptic neuronal stimulation.^{113,204} Adenosine also counterbalances the effects of DA stimulation in the basal ganglia.^{113,204}

Synthesis, Release, and Reuptake

Adenosine is derived from the breakdown of ATP, which is commonly co-released with other neurotransmitters (eg, NE, ACh, glutamate) into the synapse before subsequent degradation by ectonucleotidases (Fig. 14–15). During times of adequate oxygen delivery and oxidative phosphorylation, intracellular ATP concentrations are many times greater than those of adenosine, with normal intracellular adenosine concentrations ranging from 50 to 300 nM.⁶⁰ Intracellular adenosine concentrations increase rapidly during ischemia, hypoxia, or elevated metabolic activity (eg, seizures).^{59,113} A bidirectional equilibrative nucleoside transporter (ENT) typically moves adenosine from the synapse back into the neuron under normal conditions, but can reverse adenosine transport when intracellular adenosine concentrations become elevated (Fig. 14–15).¹¹³ The normal overall cellular preference is to convert adenosine back to ATP via adenosine kinase, but some adenosine also undergoes conversion to inosine by adenosine deaminase.¹¹³ Synaptic adenosine then activates adenosine receptors on neuronal and non-neuronal tissue (eg, vasculature). The actions of adenosine are terminated by reuptake into glial cells and neurons (Fig. 14–15).^{113,204} Exogenously administered adenosine used in the treatment of supraventricular tachycardia does not cross the blood–brain barrier and, therefore, is not centrally active. The half-life of adenosine in the blood is less than 10 seconds.

FIGURE 14–15. Adenosine's role in regulating excitatory neurotransmission, using glutamate as an example. In this example, glutamate excites a postsynaptic neuron by activating metabotropic glutamate receptors (mGluR1) [1]. ATP enters the synapse when glutamate is released. Adenosine formed from metabolism of ATP within the synapse [3] binds to postsynaptic A_1 receptors [2], which open K^+ channels to inhibit the neuron through hyperpolarization. Adenosine also activates presynaptic A_1 receptors [4] to lower intracellular Ca^{2+} concentrations, thereby impairing further glutamate release. Activation of presynaptic A_2 receptors has the opposite effect, enhancing glutamate exocytosis [11]. After uptake by ENT [5], adenosine is acted upon either by adenosine kinase (AK) [7] to form AMP, or by adenosine deaminase (ADA) [6] to form inosine. Adenosine also binds to neuronal postsynaptic A_2 receptors (especially in the striatum) and to vascular A_2 receptors to cause vasodilation [8]. A_3 receptors [9] are not activated by normal concentrations of adenosine. During times of excessive catabolism (eg, seizures, hypoglycemia, stroke) when intracellular adenosine concentrations rise markedly, adenosine moves into the synapse through reverse transport via ENT [5]. Resultant stimulation of A_1 and A_2 receptors results in inhibitory actions to decrease oxygen requirements and to increase substrate delivery through vasodilation as described above. However, the resultant stimulation of A_3 receptors [9] may contribute to neuronal damage and death. Xenobiotics in Table 14–12 act to inhibit adenosine uptake [5]; to inhibit ADA [6]; to inhibit AK [7]; to increase adenosine release; and to antagonize A_1 [2,4] and A_2 [8,11] receptors. ADP = adenosine diphosphate; ATP = adenosine triphosphate; cAMP = cyclic adenosine monophosphate; ENT = equilibrative nucleoside transporter; G = G protein; IP₃ = inositol triphosphate.

Adenosine Receptors

The purine P_1 receptor family comprises four adenosine receptor subtypes linked to G proteins: A_1 , A_{2A} , A_{2B} , and A_3 .⁶⁰ Postsynaptic A_1 stimulation results in K^+ channel opening and K^+ efflux, with subsequent hyperpolarization of the neuron (Fig. 14–15). Evidence suggests that G protein-mediated Cl^- influx may explain postsynaptic hyperpolarization by A_1 activation in some cases. Presynaptic A_1 stimulation modifies voltage-dependent Ca^{2+} channels, lessening Ca^{2+} influx during depolarization, which limits exocytosis of neurotransmitter. Therefore, activation of A_1 receptors prevents release of neurotransmitters presynaptically and inhibits their responses postsynaptically.¹¹³

In the central and autonomic nervous systems, A_1 receptors reside on presynaptic and postsynaptic membranes, where

they serve as inhibitory modulators for numerous neurotransmitter systems; they are particularly prevalent in association with glutamatergic neurons in the CNS.¹¹³ The A₁ receptor is prevalent throughout the central nervous system, with high concentrations in the cerebral cortex, hippocampus, cerebellum, thalamus, brain stem, and spinal cord. Agonism of A₁ receptors by adenosine produces sedation, neuroprotection, anxiolysis, temperature reduction, anticonvulsant activity, and spinal analgesia.^{60,204}

Peripheral A₁ receptor activation produces bronchoconstriction, decreased glomerular filtration, decreased heart rate, slowed atrioventricular conduction, and decreased atrial myocardial contractility.⁶⁰

In the CNS, A_{2A} receptors demonstrate limited distribution. They are concentrated on cerebral vasculature and produce vasodilation when stimulated.⁶⁰ Additionally, A_{2A} receptors are especially prevalent on neurons in the striatum, where they inhibit the activity of D₂ receptors.²⁰⁴ Antagonism of A_{2A} receptors in the striatum increases dopamine-mediated motor activity without the dyskinesia that commonly occurs with DA agonists.^{113,204} Some A_{2A} receptors are found presynaptically as heterodimers with A₁ receptors. They act to diminish the inhibition of presynaptic A₁ receptors when adenosine concentrations increase.¹¹³ Under normal conditions the presynaptic A_{2A} receptors are relatively inactive.

A_{2B} receptors are expressed diffusely throughout the brain, and are most commonly identified on glial cells. A_{2B} receptors demonstrate low affinity for adenosine, and little is known of their physiologic role.²⁰⁴ A_{2A} and A_{2B} receptors are coupled to G_s. The rise in cAMP concentration resulting from A_{2A} activation on cerebral vasculature and elsewhere explains vasodilation.^{60,204} For example, peripheral A₂ receptor activation also results in coronary artery vasodilation.⁶⁰

A₃ receptors express low affinity for adenosine. In the CNS, A₃ receptors are expressed primarily in the hippocampus and thalamus. A₃ receptors act through G proteins to decrease adenylate cyclase activity and increase phospholipase C activity.¹¹³ The low concentrations of adenosine found during normal metabolism minimally activate A₃ receptors to produce inhibitory effects. During times of excessive ATP degradation (eg, hypoxia, seizures), adenosine accumulates at and activates A₃ receptors to produce complex responses that appear to enhance ischemic cellular injury and death, at least in part through disinhibition of presynaptic metabotropic glutamate receptor responses. Thus, A₃ receptor antagonists are being examined for neuroprotective actions.⁵⁹

Adenosine and Seizure Termination

In humans and in animal models of status epilepticus, including those from xenobiotics, there are two alternating phases of electrical activity noted on electroencephalography. Periods of high-frequency spike activity (ictal) are accompanied by marked increases in cerebral oxygen consumption and metabolic requirements and alternate with interictal periods of isolated spike waves during which metabolic demands are less. The high-frequency phase lasts only a few minutes before suddenly terminating, sometimes with a few seconds of electrocerebral silence. A gradual increase in electrical activity during the interictal phase eventually leads to a recurrence of high-frequency spike activity.⁷

These periodic, spontaneous self-terminations of high-frequency electrical activity initially occur before neurons exhaust oxygen and energy supplies and result from adenosine released from depolarizing neurons and glial cells.^{7,48} Adenosine acts on presynaptic receptors to prevent further release of excitatory neurotransmitters and acts on postsynaptic receptors to inhibit their actions.^{48,204}

Any xenobiotic that directly or indirectly enhances adenosine’s action at A₁ receptors in the brain will usually exhibit anticonvulsant activity. Conversely, A₁ receptor antagonists lower the seizure threshold and make seizure termination more difficult and less likely to respond to anticonvulsants. Xenobiotics that antagonize A_{2A} receptors produce cerebral vasoconstriction and may limit oxygen delivery during times of increased demand.⁷

Xenobiotics

Table 14–12 provides examples of xenobiotics that affect adenosine receptors.

TABLE 14–12. Examples of Xenobiotics Affecting Adenosine Receptors	
Adenosine agonism

Theophylline

^aEthanol's inhibition of adenosine uptake may, at least in part, be explained by metabolism to acetate.

Direct Adenosine Agonists. ADAC (adenosine amine congener) is a direct A₁ receptor agonist used in the treatment of Huntington disease.⁹ Regadenoson is a selective A_{2A} agonist clinically used as a diagnostic agent for pharmacological stress testing.⁶⁰ Tecadenoson is a selective A₁ receptor agonist that is used for treatment of supraventricular tachycardia.^{52,60}

Indirect Adenosine Agonists. Papaverine and dipyridamole inhibit adenosine reuptake.^{60,61} Like other adenosine agonists, papaverine and dipyridamole demonstrate anticonvulsant activity when injected into the CNS. Such actions are not achievable with safe systemic doses. Sevoflurane and isoflurane are two commonly used general anesthetic gases with adenosine agonist activities.⁶⁰

In addition to their actions at GABA_A receptors, benzodiazepines inhibit adenosine reuptake.¹¹² This may explain observations that methylxanthines, potent adenosine receptor antagonists, have reversed benzodiazepine-induced sedation in humans. The potencies of benzodiazepines as inhibitors of adenosine uptake show good correlation with clinical anxiolytic and anticonflict potencies, suggesting that such inhibition contributes to their action. The anticonvulsant effect of large doses of flumazenil also results, at least in part, from inhibition of adenosine uptake. Carbamazepine inhibits adenosine reuptake, although this is not thought to account for most anticonvulsive action.

Adenosine may mediate many of the acute and chronic motor effects of ethanol on the brain. Ethanol, possibly through its metabolite, acetate, prevents adenosine reuptake, raising synaptic adenosine concentrations.⁶ Excessive stimulation of several adenosine receptors in the cerebellum may explain much of the motor impairment from low ethanol concentrations. In fact, animals made tolerant to ethanol develop cross-tolerance to adenosine agonists. In mice, adenosine receptor agonists increase ethanol-induced incoordination, while adenosine antagonists decrease this intoxicating response.⁶

There are numerous inhibitors of adenosine reuptake, including propentofylline, nimodipine, cyclic antidepressants, and other calcium channel blockers.^{154,156} A₁ receptors located at the spinal cord are important modulators of pain transmission. Cyclic antidepressant-induced inhibition of adenosine uptake may explain some of their effectiveness in treating neuropathic pain.⁶¹ The analgesic effectiveness of opioids can be partially attributed to their ability to increase the release of adenosine within the spinal cord.^{12,61}

Dipyridamole inhibits adenosine deaminase, raising adenosine concentrations. During times of elevated adenosine concentrations that occur with cardiac or cerebral ischemia, adenosine further enhances adenosine's beneficial actions by three mechanisms: inhibition of adenosine kinase, inhibition of adenosine deaminase, and inhibition of adenosine reuptake.¹⁴³

Adenosine Antagonists. The main adenosine antagonists of toxicologic concern are methylxanthines. Theophylline and caffeine are selective P₁ antagonists, blocking both A₁ and A₂ receptors.^{7,12} The response to methylxanthines by A₃ receptors varies widely, depending on the species. Human A₃ receptors demonstrate very low affinity for methylxanthines.⁶⁰

Peripherally, methylxanthines produce excessive release of catecholamines from peripheral nerve endings (and probably the adrenal gland) by blocking presynaptic A₁ receptors. In turn, catecholamine-mediated responses are exaggerated by blockade of inhibitory postsynaptic A₁ receptors on end organs.⁶⁰

Centrally, enhanced release and actions of excitatory neurotransmitters (eg, glutamate) explain methylxanthine-induced convulsions that are frequently refractory to anticonvulsants. The reasons why theophylline convulsions carry such a high mortality stem from lack of A₁-mediated self-termination (continual high-frequency spike activity and large metabolic demands), compounded by vasoconstriction caused by blockade of A₂ receptors.

Like phenytoin, the major anticonvulsant effect of carbamazepine results from Na⁺ channel blockade. Unlike phenytoin, carbamazepine antagonizes A₁ receptors.^{33,41} This may explain the higher frequency of seizures after carbamazepine

overdose than after phenytoin overdose. The absence of A₂ blockade by carbamazepine theoretically allows for increases in cerebral blood flow to meet metabolic demands of the seizing brain.

SUMMARY

- Neurotransmitter systems share common physiologic features, including neurotransmitter reuptake, vesicle membrane pumps, ion trapping of neurotransmitters within vesicles, calcium-dependent exocytosis, and receptors coupled to either G proteins or to ion channels.
- It is not surprising, then, that a single xenobiotic frequently produces effects on several different neurotransmitter systems. As the number of new xenobiotics encountered by man continues to grow, an understanding of their molecular actions in the nervous system helps to anticipate and better understand various pharmacologic and adverse effects resulting from therapeutic or toxic doses.

15 WITHDRAWAL PRINCIPLES

Richard J. Hamilton

In the central nervous system (CNS), excitatory neurons fire regularly, and inhibitory neurons inhibit the transmission of these impulses. Whenever action is required, the inhibitory tone diminishes, permitting the excitatory nerve impulses to travel to their end organs. Thus, all action in human neurophysiology can be considered to result from disinhibition.

Tonic inhibition (sustained, as opposed to phasic or transient inhibition) triggered by the constant presence of a xenobiotic produces an adaptive change in the affected neuron such that the constant presence of that xenobiotic is required to prevent dysfunction. A withdrawal syndrome occurs when the constant presence of this xenobiotic is removed or reduced and the adaptive changes persist. Withdrawal is a dysfunctional condition in which tonic inhibitory neurotransmission is significantly reduced, essentially producing excitation (Fig. 15–1). Every withdrawal syndrome has two characteristics: (1) a preexisting physiologic adaptation to a xenobiotic, the continuous presence of which prevents withdrawal, and (2) decreasing concentrations of that xenobiotic. In contrast, simple tolerance to a xenobiotic is characterized as a physiologic adaptation that shifts the dose–response curve to the right; that is, greater amounts of a xenobiotic are required to achieve a given effect. Physiologic dependence, generally simply called dependence, occurs when the absence of the xenobiotic leads to the development of a specific withdrawal syndrome. Dependence needs to be distinguished from addiction, which is compulsive drug-seeking behavior. The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), uses the term substance use to combine the DSM-IV disorders of substance abuse and substance dependence.³

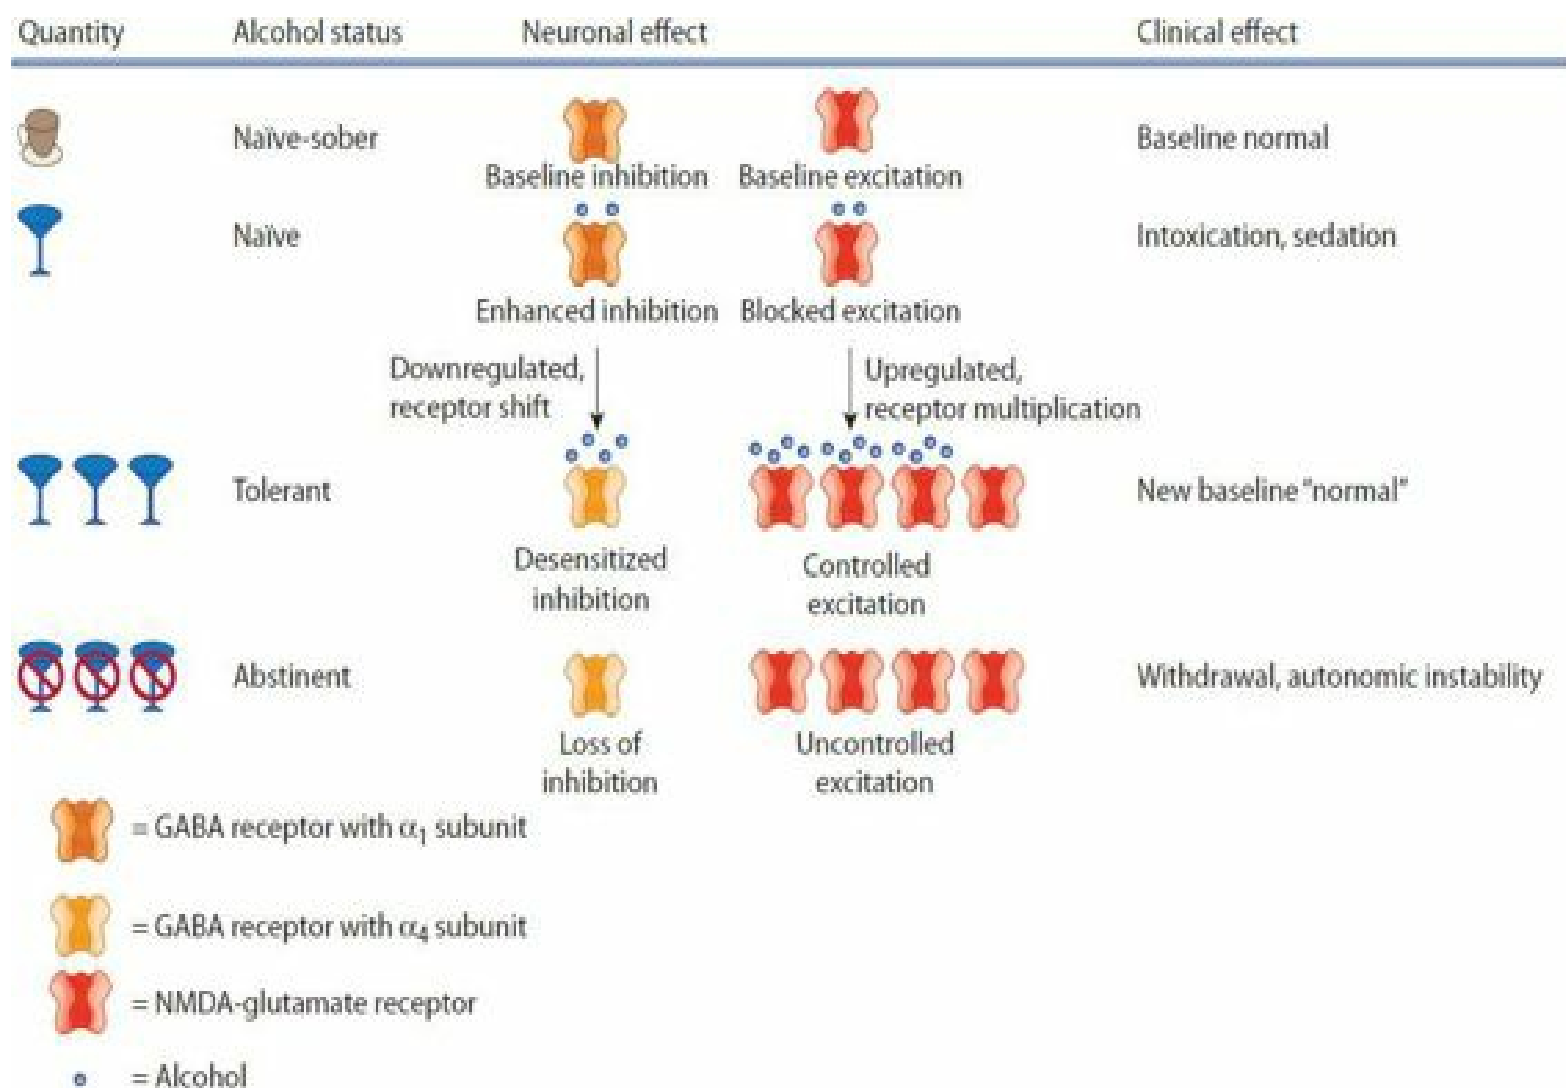

FIGURE 15–1. Alcohol intoxication, tolerance, and withdrawal. Alcohol consumption in an alcohol-naïve person

produces intoxication and sedation by simultaneous agonism at the γ -aminobutyric acid (GABA) receptor–chloride channel complex and antagonism at the N-methyl-D-aspartate (NMDA)-glutamate receptor. Continuous alcohol consumption leads to the development of tolerance through changes in both the GABA receptor–chloride channel complex (a subunit shift from α_1 to α_4 , resulting in reduced sensitivity to the sedating effects of alcohol) and the NMDA subtype of glutamate receptor (upregulation in number, resulting in enhanced wakefulness). There is conceptually a concentration at which the tolerant patient may appear clinically normal despite having an elevated blood alcohol concentration. Tolerant patients who are abstinent lose the tonic effects of alcohol on these receptors, resulting in withdrawal.

Withdrawal is manifested by either of the following: (1) a characteristic withdrawal syndrome for the substance, or (2) the same (or a closely related) substance is taken to relieve withdrawal symptoms. Note that either criterion fulfills this definition. Logically, all syndromes have the first criterion, so it is the presence of the second criterion that is critical to understanding physiology and therapy.

For the purposes of defining a unifying pathophysiologic pattern of withdrawal syndromes, this chapter considers syndromes in which both features are present. An analysis from this perspective distinguishes xenobiotics that affect the inhibitory neuronal pathways from those that affect the excitatory neuronal pathways, such as cocaine. According to this definition, cocaine does not produce a withdrawal syndrome but rather a postintoxication syndrome that often results in lethargy, hypersomnolence, movement disorders, and irritability. Although referred to as withdrawal, this syndrome does not meet the definition for a withdrawal syndrome because the same (or a closely related) substance is not taken to relieve or avoid withdrawal symptoms. This postintoxication syndrome, the so-called “crack crash” or “washed-out syndrome,” is caused by prolonged use of cocaine, and patients ultimately return to their premorbid function without intervention. This distinction is important for toxicologists, because (1) withdrawal syndromes that demonstrate both features of the DSM-IV-TR criteria are treated with reinstatement and gradual withdrawal of a xenobiotic that has an effect on the receptor and (2) withdrawal syndromes that do not demonstrate the second feature require only supportive care and resolve spontaneously. The term “drug discontinuation syndromes” has been used in particular with serotonin reuptake inhibitors to describe the symptoms that result when a drug used therapeutically is discontinued but this is in fact a withdrawal syndrome. Addiction and dependence are terms often used in the context of the psychosocial aspects of xenobiotic use and are meant to convey the continued use of a xenobiotic despite adverse consequences.

Finally, withdrawal syndromes are best described and treated according to the class of receptors primarily affected because this concept also organizes the approach to patient care. For each receptor and its agonists, research has identified genomic and nongenomic effects that produce neuroadaptation and withdrawal syndromes. Six mechanisms appear to be involved: (1) genomic mechanisms via mRNA, (2) second-messenger effects via protein kinases, cyclic adenosine monophosphate (cAMP),^{17,19} or calcium ions, (3) receptor endocytosis, (4) expression of various receptor subtypes depending on location within the synapse (synaptic localization), (5) intracellular signaling via effects on other receptors, and (6) neurosteroid modulation. Some or all of these mechanisms are demonstrated in each of the known withdrawal syndromes.^{23,24} These mechanisms develop in a surprisingly rapid fashion and modify the receptor and its function in such complex ways as to depend on the continued presence of the xenobiotic to prevent dysfunction.^{21,28,37,43,44}

GABA_A RECEPTORS (BARBITURATES, BENZODIAZEPINES, ETHANOL, VOLATILE SOLVENTS)

GABA_A receptors are part of a superfamily of ligand-gated ion channels, including nicotinic acetylcholine receptors and glycine receptors, which exist as pentamers arranged around a central ion channel. When activated, they hyperpolarize the postsynaptic neuron by facilitating an inward chloride current (without a G protein messenger), decreasing the likelihood of the neuron firing an action potential. γ -aminobutyric acid type A (GABA_A) receptors have separate binding sites for GABA, barbiturates, benzodiazepines, loreclezole, and picrotoxin (Chap. 14).³¹ Barbiturates and benzodiazepines bind to separate receptor sites and enhance the affinity for GABA_A at its receptor site.

The GABA receptor is a pentamer comprised of two α subunits, two β subunits, and one additional subunit, most commonly γ , which is a key element in the benzodiazepine binding site. Each receptor has two GABA binding sites that are located in a homologous position to the benzodiazepine site between the α and β subunits. Although the mechanism is unclear, benzodiazepines have no direct functional effect without the presence of GABA. Conversely, certain barbiturates (perhaps all, in a dose-dependent manner) and propofol can directly increase the duration of channel opening, thereby producing a net increase in current flow without GABA binding. This process has therapeutic implications and accounts for why high-dose barbiturates are nearly universally successful in stopping status epilepticus and treating severe withdrawal.

This prototypical pentameric GABA_A receptor assembly is derived from permutations and combinations of two, three, four, or even five different subunits. The subtypes of GABA receptors can even vary on the same cell. In fact, GABA receptors are heterogeneous receptors with different subunits and distinct regional distribution. Although the preponderance of subtypes $\alpha_1\beta_2\gamma_2$, $\alpha_2\beta_3\gamma_2$, and $\alpha_3\beta_3\gamma_2$ accounts for 75% of GABA receptors, there are at least 16 others of import.⁴⁴ The

recognition of additional subunits of GABA_A receptors has permitted the development of targeted pharmaceuticals, such as zolpidem.⁵

Previously, ethanol was thought to have GABA receptor activity, although a clearly identified binding site was not evident. Traditional explanations for this effect included (1) enhanced membrane fluidity and allosteric potentiation (so-called cross-coupling) of the five proteins that construct the GABA_A receptor, (2) interaction with a portion of the receptor, and/or (3) enhanced GABA release. Research with chimeric reconstruction of GABA_A and N-methyl-D-aspartate (NMDA) channels demonstrates highly specific binding sites for high doses of ethanol that enhance GABA_A and inhibit NMDA receptor-mediated glutamate neurotransmission. However, research has not clarified whether ethanol at low doses is a direct agonist of GABA_A receptors or a potentiator of GABA_A receptor binding.³²

Ethanol exhibits six mechanisms of adaptation to chronic exposure and is the prototypical xenobiotic for studying neuroadaptation and withdrawal.^{11,23,27} These six mechanisms appear to apply to benzodiazepines as well.^{1,32} The mechanisms are (1) altered GABA_A receptor gene expression via alterations in mRNA and peptide concentrations of GABA_A receptor subunits in numerous regions of the brain (genomic mechanisms), (2) posttranslational modification through phosphorylation of receptor subunits with protein kinase C (second-messenger effects), (3) subcellular localization by an increased internalization of GABA_A receptor α_1 -subunit receptors (receptor endocytosis), (4) modification of receptor subtypes with differing affinities for agonists to the synaptic or nonsynaptic sites (synaptic localization), (5) regulation via intracellular signaling by the NMDA, acetylcholine, serotonin, and β -adrenergic receptors, and (6) neurosteroidal modulation of GABA receptor sensitivity and expression.^{9,17,25} Furthermore, changes in GABA_A subunit composition and function are evident within one hour of administration of a single dose of ethanol.²⁶

Intracellular signaling via the NMDA subtype of the glutamate receptor appears to explain the “kindling” hypothesis, in which successive withdrawal events become progressively more severe.^{7,27} The activity of excitatory neurotransmission increases the more it fires, a phenomenon known as long-term potentiation, and is the result of increased activity of mRNA and receptor protein expression, a genomic effect of intracellular signaling.⁴¹ As NMDA receptors increase in number and function (upregulation) and GABA_A receptor activity diminishes, withdrawal becomes more severe.^{16,27,40} The dizocilpine (MK-801) binding site of the NMDA receptor appears to be the major contributor, and this effect is recognized in neurons that express both NMDA and GABA_A receptors.² When alcohol or any xenobiotic with GABA agonist activity is withdrawn, inhibitory control of excitatory neurotransmission, such as that mediated by the now upregulated NMDA receptors, is lost.²⁸ This loss results in the clinical syndrome of withdrawal: CNS excitation (tremor, hallucinations, seizures), and autonomic stimulation (tachycardia, hypertension, hyperthermia, diaphoresis) (Chap. 81).³⁷

Volatile solvents, such as gasoline, diethyl ether, and toluene, are widely abused xenobiotics whose effects also appear to be mediated by the GABA receptor (Chap. 84).^{35,39} These solvents can produce CNS inhibition and anesthesia at escalating doses via the GABA_A receptor in a fashion similar to that of ethanol.^{6,18,46}

GABA_B RECEPTORS (GHB AND BACLOFEN)

GABA_B agonists such as γ -hydroxybutyric (GHB) acid, GHB precursors and analogs, and baclofen have similar clinical characteristics with regard to adaptation and withdrawal.⁴⁷ The GABA_B receptor is a heterodimer of the GABA_{B1} and GABA_{B2} receptors. Unlike GABA_A, the GABA_B receptor couples to various effector systems through a signal-transducing G protein.^{10,47} GABA_B receptors mediate presynaptic inhibition (by preventing Ca²⁺ influx) and postsynaptic inhibition (by increasing K⁺ efflux). The postsynaptic receptors appear to have an inhibitory effect similar to that of the GABA_A receptors, though the mechanism differs. The presynaptic receptors provide feedback inhibition of GABA release.

GHB is a naturally occurring inhibitory neurotransmitter with its own distinct receptor (Chap. 83).⁴ Physiologic concentrations of GHB activate at least two subtypes of a distinct GHB receptor (antagonist-sensitive and antagonist-insensitive). However, at supraphysiologic concentrations, such as those that occur after overdose and abuse, GHB binds directly to the GABA_B receptor and is metabolized to GABA (which then activates the GABA_B receptor). The GHB withdrawal syndrome clinically resembles the withdrawal syndrome from ethanol and benzodiazepines and can be severe. In most cases, distinctive clinical features of GHB withdrawal are the relatively mild and brief autonomic instability and the persistence of psychotic symptoms.⁴²

Baclofen is also a GABA_B agonist. The presynaptic and postsynaptic inhibitory properties of baclofen allow it, paradoxically, to cause seizures associated with both acute overdose (because of decreased release of presynaptic GABA via autoreceptor stimulation) and withdrawal. Withdrawal is probably a result of the loss of the chronic inhibitory effect of baclofen on postsynaptic GABA_B receptors. Discontinuation of baclofen produces hyperactivity of neuronal Ca²⁺ channels

(N, P/Q type),¹² leading to seizures, hypertension, hallucinations, psychosis, and coma. However, these manifestations may not differ clinically from the withdrawal symptoms of GABA_A agonists.

Typically, the development of a baclofen withdrawal occurs 24 to 48 hours after discontinuation or a reduction in the dose of baclofen. Case reports highlight the development of seizures, hallucinations, psychosis, dyskinesias, and visual disturbances. Additionally the intrathecal baclofen pump has become an effective replacement for oral dosing, but severe withdrawal can occur when the pump malfunctions or becomes disconnected. Reinstatement of the prior baclofen-dosing schedule appears to resolve these symptoms within 24 to 48 hours. Benzodiazepines and GABA_A agonists (not phenytoin) are the appropriate treatment for seizures induced by baclofen withdrawal.³⁸

OPIOID RECEPTORS (OPIOIDS)

Similar to the behavior of ethanol and GABA_A receptors, opioid binding to the opioid receptors results in a series of genomic and nongenomic neuroadaptations, especially via second-messenger effects. When opioids bind to opioid receptors they alleviate pain by inhibiting neurons, while activating G_s proteins and stimulating K⁺ efflux currents. The opioid receptors are also linked to the G_{i/o} proteins. They act through adenylyl cyclase and inactivate inward Na⁺ current, thus suppressing the intrinsic excitability of a neuron (Chap. 38).

Chronic use of all xenobiotics with opioid-receptor affinity results in a decreased efficacy of the receptor to open potassium channels by genomic mechanisms and second-messenger effects. Following chronic opioid use, the expression of adenylyl cyclase increases through activation of the transcription factor known as cAMP response element-binding protein (CREB) (Fig. 15–2).^{15,29} This situation results in upregulation of cAMP-mediated responses such as the inward Na⁺ channels responsible for intrinsic excitability. The net effect is that only higher concentrations of opioids result in analgesia and other opioid effects. In the dependent patient, when opioid concentrations drop, inward Na⁺ flux occurs unchecked, and the patient experiences the opioid withdrawal syndrome. The clinical findings associated with this syndrome are largely a result of uninhibited activity at the locus ceruleus.^{21,29}

FIGURE 15–2. Immediate and long-term effects of opioids. The immediate effects of both opioids and α₂-adrenergic agonists are to increase inhibition through enhanced potassium efflux and inhibited sodium influx. Long-term effects alter gene expression to enhance sodium influx and restore homeostasis. CREB = cAMP response element-binding protein; ADC = adenylyl cyclase; PKC = protein kinase C. (μ) = α₂-adrenergic receptor.

Furthermore, opioid receptors and central α₂-adrenergic receptors both exert an analogous effect on the potassium channel in the locus ceruleus. Clonidine binds to the central α₂-adrenergic receptor and stimulates potassium efflux, as do opioids, and produces similar clinical findings, which explains why clonidine has efficacy in treating certain aspects of the opioid withdrawal syndrome (cross tolerance). In addition, the antagonistic effect of naloxone at the opioid receptor seems

to partially reverse the effect of clonidine on this shared potassium efflux channel.

Rapid and ultrarapid opioid detoxification are forms of intentional iatrogenic withdrawal that use opioid antagonists to accelerate a return to premorbid receptor physiology. In theory, although not necessarily in practice, inducing opioid withdrawal under general anesthesia with high-dose opioid antagonists permits the transition from drug dependency to naltrexone maintenance without enduring an intense withdrawal syndrome (Chap. 38).^{13,14, 20}

α_2 -ADRENERGIC RECEPTORS (CLONIDINE)

In a manner related to their role in treating opioid withdrawal, prolonged exposure to clonidine and related medications are associated with a withdrawal syndrome. α_2 -Adrenergic receptors are located in the central and peripheral nervous systems. Clonidine is a central and peripheral α_2 -adrenergic agonist. Stimulation of central presynaptic α_2 -adrenergic receptors inhibits sympathomimetic output and results in bradycardia and hypotension. Within 24 hours after the discontinuation of chronic clonidine use, norepinephrine concentrations rise as a result of enhanced efferent sympathetic activity. This increase results in hypertension, tachycardia, anxiety, diaphoresis, and hallucinations.

Dexmedetomidine is a medication that is gaining use as a sedative in the intensive care unit. Like clonidine it is a central and peripheral presynaptic α_2 -adrenergic agonist, but dexmedetomidine has greater specificity for the α_2 receptor and hence stronger sedative properties. It cannot be given in bolus doses because it causes hypertension and tachycardia by stimulating peripheral α_2 receptors on vascular smooth muscle (much like the initial phase of a clonidine overdose).²²

Dexmedetomidine has been used as an adjunct to treat alcohol, benzodiazepine, and opioid withdrawal and is reported to cause less respiratory depression than benzodiazepines but more bradycardia.³⁴ Importantly, dexmedetomidine has a withdrawal syndrome exactly like that of clonidine, including hypertension, tachycardia, and agitation. In fact, clonidine has been used to treat this withdrawal successfully.^{36,45}

ADENOSINE (A) RECEPTORS (CAFFEINE)

The release of most neurotransmitters is accompanied by the passive release of adenosine as a byproduct of adenosine triphosphate (ATP) breakdown. The released adenosine binds to postsynaptic A_1 receptors where it typically has inhibitory effects on the postsynaptic neuron. It also binds to presynaptic A_1 autoreceptors to limit further release of neurotransmitters. A_2 receptors are found on the cerebral vasculature and peripheral vasculature where stimulation promotes vasodilation. Caffeine and other methylxanthines, such as theophylline, antagonize the inhibitory effect of adenosine, primarily on postsynaptic A_1 receptors. As a result, acute use results in increases in heart rate, ventilation, gastrointestinal motility, gastric acid secretion, and motor activity. Chronic caffeine use results in tolerance and the above symptoms diminish. Caffeine use upregulates A_1 receptors by a variety of mechanisms, including increases in receptor number, increases in receptor affinity, enhancement of receptor coupling to the G protein, and increases in G protein-stimulated adenylyl cyclase. An animal study demonstrates that the adenosine receptor has a threefold increase in affinity for adenosine at the height of withdrawal symptoms. This model suggests that long-term caffeine administration results in an increase in receptor affinity for adenosine, thus restoring a state of physiologic balance (normal motor inhibitory tone). When caffeine is withdrawn, the enhanced receptor affinity results in a strong adenosine effect and clinical symptoms of withdrawal: headache (cerebral vasodilation), fatigue, and hypersomnia (motor inhibition).

ACETYLCHOLINE RECEPTORS (NICOTINE)

A nicotinic receptor is a type of acetylcholine receptor located in the autonomic ganglia, adrenal medulla, CNS, spinal cord, neuromuscular junction, and carotid and aortic bodies. Nicotinic receptors are fast-response cation channels that are not coupled to G proteins, distinguishing them from muscarinic receptors, which are coupled to G proteins. Nicotinic acetylcholine receptors have both excitatory and inhibitory effects. As in other withdrawal syndromes, changes brought on by chronic use of nicotinic agonists, such as nicotine in cigarettes, appear to be related to selective upregulation of cAMP.^{8,43}

SEROTONIN REUPTAKE INHIBITORS DISCONTINUATION SYNDROME

As mentioned above, drug discontinuation syndrome is a term used to describe the withdrawal syndrome associated with the therapeutic use of serotonin reuptake inhibitors. It meets the definition of withdrawal syndromes in that symptoms begin when xenobiotic concentrations drop, and the syndrome abates when the xenobiotic is reinstated.³⁰ Headache, nausea, fatigue, dizziness, and dysphoria are commonly described symptoms. The condition appears to be uncomfortable but not life threatening, rapidly resolves with reinstatement of a xenobiotic of the same class, and slowly resolves when the

medication is discontinued after a more gradual taper (Chap. 75).³³

SUMMARY

- Withdrawal occurs when a xenobiotic that has produced adaptive changes in a neuron is removed.
- The treatment of a withdrawal syndrome generally involves readministration of the xenobiotic from which the patient is withdrawing.
- In some situations, crosstolerant xenobiotics can be administered. Examples include the use of benzodiazepines and barbiturates to treat ethanol withdrawal or clonidine for opioid withdrawal.

SECTION II

PATHOPHYSIOLOGIC BASIS: ORGAN SYSTEMS

16 ELECTROPHYSIOLOGIC AND ELECTROCARDIOGRAPHIC PRINCIPLES

Cathleen Clancy

ELECTROPHYSIOLOGIC PRINCIPLES

The clinical tool most commonly used to assess cardiac function is the surface electrocardiogram (ECG). The ECG records the sum of the electrical changes occurring within the myocardium. The electrophysiologic basis of cardiac function and the ECG are complex and are subject to alteration by numerous xenobiotics. Ion currents flowing through various ion channels are responsible for cardiac function. Electrophysiologic studies have identified the functional types of membrane receptors and ion channels. Molecular genetic studies have identified the gene coding for the key cardiac ion channels and have elucidated the structural and physiologic relationships that lead to the toxic effects of many xenobiotics. These channels are critical for maintenance of the intracellular ion concentrations necessary for action potential development, impulse conduction throughout the heart, and myocyte contraction. This chapter will first review the individual ion channels and their currents, and then summarize their contribution and effects on the ECG.

ION CHANNELS OF THE MYOCARDIAL CELL MEMBRANE

Sodium Channels

The voltage-sensitive sodium channels are responsible for the initiation of depolarization of the myocardial membrane. All currently identified voltage-sensitive channels, including the sodium and calcium channels, have structures similar to the potassium channel assembly. The sodium channel gene encodes a single protein that contains four functional domains (D I to D IV). Each of these domains has the six membrane-spanning regions characteristic of the voltage-gated potassium channel and is structurally similar to an α subunit of the potassium channel (Fig. 16–1A). The single, large α subunit of the sodium channel assembles with regulatory β subunits to form the functional unit of the sodium channel. The best characterized of the sodium channels, the SCN5A gene-encoded α channel, is inactivated by xenobiotic interactions between the D III and the D IV domains to physically block the inner mouth of the sodium channel pore.³² Six specific receptor sites are identified on the α subunit with different xenobiotics binding at specific sites: tetrodotoxin, saxitoxin, conotoxin (site 1); veratridine, batrachotoxin, grayanotoxin (site 2); α scorpion toxins, sea anemone toxins (site 3); β -scorpion toxins (site 4); brevetoxins, ciguatoxins (site 5); delta conotoxins (site 6); and local anesthetic and related antidysrhythmic and antiepileptic binding at another receptor site.¹⁵

FIGURE 16–1. Structure of the sodium and potassium channels. (A) The structure of the α subunit of the sodium channel. The protein molecule has 4 functional domains (D I–D IV) each analogous to one of the potassium channel α subunits. One of these molecules assembles with β subunits to form the membrane sodium channel. (B) The structure of the α subunit of the voltage gated potassium channel. The protein molecule has six membrane spanning regions (S1–S6); the voltage sensitive region is S4 and the actual ion channel is located between S5 and S6. Four of these α subunits assemble with four β subunits to form the potassium channel complex.

Potassium Channels

Ion channels that change their conductance of current with changes in the transmembrane voltage potential are called rectifying channels. The voltage sensitive potassium channels are categorized based upon their speed of activation and their voltage response. They include the “delayed rectifier” potassium currents, particularly the I_{K_r} (rapidly activating) and the I_{K_s} (slowly activating) channels.⁴⁶

The various voltage gated potassium channels share an underlying structural similarity. The α subunit is a protein molecule with six membrane-spanning α -helical domains, termed S1 to S6 (Fig. 16–1B). The pore domain is located between the S5 and S6 regions of the α subunit, and the S4 region is the voltage sensor region.^{32,55} Four of the α subunits encoded by the KvLQT1 gene assemble with β units encoded by the minK gene (originally thought to be the minimal potassium channel subunit) to form the I_{K_s} potassium channel.³² Human ether a-go-go related gene (HERG) encodes the α subunit that assembles with β subunit proteins encoded by the minK related protein 1 (MiRPI) gene to form the I_{K_r} potassium channel. The C-terminus region of the α subunit encoded by HERG has a cyclic nucleotide binding domain and an N-terminus region similar to domains involved in signal transduction in cells.³²

Many xenobiotics interact with the HERG-encoded subunit of the potassium channel to reduce the current through the I_{K_r} channel and prolong the action potential duration. The HERG α subunit of the channel is particularly susceptible to xenobiotic-induced interactions due to two important differences from the other channels. First, the S6 domain of the HERG channel has aromatic domains on the inner cavity pore that can bind to aromatic xenobiotics. Additionally, the inner cavity and entrance of the HERG channel is larger than the other voltage-gated potassium channels.³² This larger pore can accommodate larger xenobiotics that are then trapped within the pore when the channel closes.^{32,54,55,60}

Calcium Channels

Calcium channel conductivity across the myocardial cell membrane is critical for maintaining the appropriate duration of cell membrane depolarization and for initiation of cellular contraction. The best characterized of the calcium channels are the slow (L-type), the fast (T-type), and the ryanodine receptor calcium channel. They are more prominently involved in cardiac contractility and discussed in Chap. 17.

ION CHANNELS AND MYOCARDIAL CELL ACTION POTENTIAL

An understanding of the basic electrophysiology of the myocardial cell is essential to understand the toxicity of xenobiotics and to plan appropriate therapy. **Figure 16–2A** shows the typical action potential of myocardial cell depolarization, the electrolyte fluxes responsible for the action potential, and the resulting ECG complex. The action potentials of the contractile and the conductive cells are depicted.

FIGURE 16–2. Relationship of electrolyte movement across the cell membrane (**A**) to the action potential and the surface ECG recording (**B**) over a single cardiac cycle.

The action potential is divided into five phases: (1) phase 0, depolarization, (2) phase 1, overshoot, (3) phase 2, plateau, (4) phase 3, repolarization, and (5) phase 4, resting. Phase 0 begins when the cell is excited either by a stimulus from an adjoining cell or by spontaneous depolarization of a pacemaker cell. The stimulus causes selective voltage-gated fast sodium channels (I_{Na^+}) to open, resulting in rapid depolarization of the membrane. At the end of phase 0, the voltage-sensitive sodium channels close and a transient outward potassium current (I_{To}) occurs, resulting in a partial repolarization of the membrane—this constitutes phase 1.

During phase 2 (plateau phase), the inward depolarizing calcium currents are largely balanced by the outward repolarizing potassium currents. Voltage-sensitive calcium channels that open allow Ca^{2+} movement down the 5000–10,000 fold concentration gradient into the cell. These channels are categorized based on their conductance (fast or slow) and their sensitivity to voltage changes.^{16,51} The calcium currents (mostly the “long-lasting” current) gradually decrease as the channels inactivate. Simultaneously, the outward potassium “delayed rectifier” currents, particularly the I_{Ks} (slowly activating) current increases, terminating the plateau phase of the action potential and initiating cellular repolarization (phase 3). Other, smaller, outward potassium currents (not shown in **Fig. 16–2A**) play a lesser role in the duration of the action potential and development of phase 3, including I_{Kur} (ultra-rapid), I_{Kr} (rapidly activating), I_{Kp} (plateau), $I_{\text{K-Ach}}$ (acetylcholine-dependent), and $I_{\text{K-ATP}}$ (adenosine triphosphate-dependent) currents.

In phase 3, the rapid repolarization phase, the cell membrane repolarizes as a result of the slow delayed rectifier, I_{Ks} and to a lesser extent the other K^+ currents, the $\text{Na}^+-\text{Ca}^{2+}$ exchanger current, and the sodium/potassium pump.

Phase 4 is the resting state for much of the myocardium, except the pacemaker cells, and it corresponds to diastole in the cardiac cycle. During phases 3 and 4, active transport of Na^+ , K^+ , and Ca^{2+} against their electrochemical gradients returns the myocyte to its baseline resting state. The transmembrane electrochemical gradient is maintained during the resting state by a $\text{Ca}^{2+}-\text{Na}^+$ exchange mechanism and by ATP-dependent pumps in the membrane that together move Ca^{2+} out of the cells.⁵¹

In the pacemaker cells (**Fig. 16–2B**), during phase 4 of the action potential, gradual electrical depolarization of the membrane occurs due to potassium currents (called the I_{Kf} for “funny” or the I_{Kh} for “hyperpolarization-activated” current).^{5,19} The membrane potential gradually increases in these pacemaker cells until the threshold potential is reached, the fast inward sodium channels open, and the I_{Na} current initiates the next phase 0. This electrical impulse is then propagated via the His-Purkinje conducting system of the heart.

In addition to its role in myocardial contractility, Ca^{2+} influx is also important in pacemaker function. Although spontaneous pacemaker cell depolarization has traditionally been ascribed to inward cation current through “pacemaker channels”^{1,19} recent research suggests that it may actually be driven by rhythmic release of calcium from the sarcoplasmic reticulum.^{39,40} Regardless, Ca^{2+} fluxes play an important role in the spontaneous depolarization (phase 4) of the action potential in the sinoatrial (SA) node.⁴¹ The rate of pacemaker cell depolarization is enhanced by β -adrenergic stimulation through phosphorylation of proteins on the sarcoplasmic reticulum and by a phosphorylation-independent action of cAMP at the pacemaker channels.^{1,39} Depolarization of cells in the SA node spreads to surrounding atrial cells where it triggers the opening of fast sodium channels and impulse propagation. Calcium flux also allows normal propagation of electrical impulses via the specialized myocardial conduction tissues in the atrioventricular (AV) node.

During phases 0 to 2, the cell cannot be depolarized again with another stimulus; the cell is absolutely refractory. During the latter half of phase 3, as the calcium channels recover from their inactivated to their resting state, an electrical stimulus of sufficient magnitude may cause another depolarization; the cell is said to be relatively refractory. During phase 4, the cell is no longer refractory and any appropriate stimulus that reaches the threshold level may cause depolarization.

ELECTROCARDIOGRAPHY

The ECG measures the sum of all electrical activity in the heart. It is used extensively in medicine and its interpretation is widely understood by physicians of nearly all disciplines. It is an invaluable diagnostic tool for patients with cardiovascular complaints. However, it is also a valuable source of information in poisoned patients and has the potential to enhance and direct their care. Although it seems obvious that an ECG would be required following exposure to a medication used for cardiovascular indications, many medications with no overt cardiovascular effects at therapeutic doses are cardiotoxic in overdose. Furthermore, in patients with unknown exposures, the ECG can suggest specific xenobiotics or demonstrate electrolyte abnormalities, long before blood is drawn. For example, oropharyngeal or dermal burns in a patient whose ECG has evidence of hyperkalemia or hypocalcemia suggests exposure to hydrofluoric acid⁶⁴ (Chap. 107). Alternatively, a patient manifesting signs of the opioid toxidrome with runs of torsade de pointes might have taken methadone (Chap. 38).²⁴ QT prolongation may be a clue to the etiology of an overdose with an atypical antipsychotic such as quetiapine (Chap. 70). The ECG can also be used to predict complications of poisoning, such as seizures following a cyclic antidepressant overdose (Chap. 71). Therefore, an ECG should be examined early in the initial evaluation of most poisoned patients.

History of the ECG

In the 1900s, Willem Einthoven graphically displayed the electrical activity of the heart and named the different waves—P, QRS, and T. He called this tracing an “elektrokardiogramme,” and was awarded a Nobel Prize in 1924 for his efforts. The acronym EKG, still employed by some authors, was derived from Einthoven’s spelling. The acronym ECG, which is consistent with our current spelling of electrocardiogram, is used throughout this text.

Since this initial description, both the normal electrophysiology of the heart and the pharmacologic effects of various xenobiotics on the ECG have been described. Despite the large number, diversity, and complexity of the various cardiac toxins, there are only a limited number of electrocardiographic manifestations.

Basic Electrophysiology of an ECG

Simplistically, a positive or upward deflection on the oscilloscope is generated when an electrical force moves toward an electrical sensor or electrode, and a downward deflection occurs if the force moves away. An ECG represents the sum of movement of all electrical forces in the heart in relation to the surface electrode, and the height above baseline represents the magnitude of the force (Fig. 16–3). Only during depolarization or repolarization does the ECG tracing leave the isoelectric baseline, because it is only during these periods that measurable net currents are flowing in the heart. During the other periods, mechanical effects are occurring in the myocardium, but large amounts of current are not flowing.

FIGURE 16–3. The hexaxial reference system derived from the Einthoven equilateral triangle defining the electrical potential vectors of electrocardiography. The relationships of the original three limb leads are illustrated. The equiangular (60°) Einthoven triangle formed by leads I, II, and III is shown (dotted lines) with positive and negative poles of each of the leads indicated. Leads I, II, and III are also presented as a triaxial reference system that intersects in the center of the ventricles.

Leads

Although the reading from a single ECG lead provides an immense amount of information, to visualize the heart in a nearly three-dimensional perspective, multiple leads must be assessed simultaneously. Given the cylindrical nature of both the heart and thorax, at any given moment some of these leads will record positive voltage and others negative. The lead placement that was described and refined in the early 1900s by Einthoven forms the basis for the bipolar or limb leads, described as I, II, and III (Fig. 16–3). The Einthoven triangle is an equilateral triangle formed by the sum of these leads. Unipolar limb leads and precordial leads were subsequently added to the standard ECG. Unipolar leads were created when the limb leads were connected to a common point where the sum of the potentials from leads I, II, and III was zero. The currently used unipolar augmented (a) leads (aV_R , aV_L , and aV_F) are based on these unipolar leads (Fig. 16–4). The voltage potential of these unipolar, “augmented leads” is small, thus it is amplified by incorporating the voltage change of the other two augmented leads. Together, leads I, II, III, aV_R , aV_F , and aV_L form the hexaxial reference system that is used to calculate the electrical axis of the heart in the frontal plane. The precordial leads, called V_1 through V_6 , are also unipolar measurements of the change in electric potential measured from a central point to the sixth anterior and left lateral chest positions (Fig. 16–5). If V_2 is placed over the right ventricle, part of the initial positive ventricular deflection (QRS complex) reflects right ventricular activation, with electrical forces moving toward the electrode. The majority of the subsequent terminal negative deflection reflects activation of other muscle tissue (septum, left ventricular wall) when the electrical forces are moving away from the electrode. Recordings from each of these 12 leads (I, II, III, aV_R , aV_L , aV_F , V_1 – V_6) evaluate the heart from two different planes in 12 different positions, yielding a three-dimensional electrical “picture” of the heart, with respect to time and voltage.

FIGURE 16–4. The hexaxial reference system derived from the Einthoven equilateral triangle defining the electrical potential vectors of electrocardiography showing the relationship between cardiac anatomy and electrocardiographic leads.

FIGURE 16–5. Visualized as a cross-section, each of the chest leads is oriented through the atrioventricular (AV) node and exits through the patient's back, which is negative.

A continuous cardiac monitor often relies on recordings from one of two bipolar leads: a modified left chest lead (MCL₁) or a lead II. The recording from an MCL₁, in which the positive electrode is in the V₁ position, is similar in appearance to a V₁ recording on a 12-lead ECG. This lead visualizes ventricular activity well; however, lead II shows atrial activity (ie, the P wave) much more clearly. Right ventricular precordial leads (V₁, V₃₋₆R) are sensitive and specific for determining the presence of right ventricular infarctions, although specific applications to poisoning have not been reported.

Various Intervals and Waves

The ECG tracing has specific nomenclature to define the characteristic patterns. Waves refer to positive or negative deflections from baseline, such as the P, T, or U wave. A segment is defined as the distance between two waves, such as the ST segment, and an interval measures the duration of a wave plus a segment, such as QT or PR interval. Complexes are a group of waves without intervals or segments between them (QRS). Electrophysiologically, the P wave and PR interval on the ECG tracing represent the depolarization of the atria. The QRS complex represents the depolarization of the ventricles. The plateau is depicted by the ST segment and repolarization is visualized as the T wave and the QT interval (QT). The U wave, when present, generally represents an afterdepolarization (Fig. 16–6).

FIGURE 16–6. The normal ECG. The U wave is the small, positive deflection following the T wave. P wave, atrial depolarization; QRS, ventricular depolarization; ST segment, T wave, QT interval, and U wave, ventricular repolarization.

The P Wave

The P wave is the initial deflection on the ECG that occurs with the initiation of each new cardiac cycle.

Electrophysiology. The early, middle, and late portions of the P wave are represented sequentially by the electrical potential initiated by the sinus node. The impulse is propagated directly through the right atrial muscle, producing contraction. The impulse is also propagated by specialized conduction tissue across the interatrial septum, to produce contraction of the left atrium. Additionally, internodal pathways rapidly conduct the impulse to the AV node. The electrical excitation of the sinus node differs from that of the ventricular myocardium in that current is mediated primarily by Ca^{2+} influx via slow T-type calcium channels, and I_{Kf} potassium currents (f for “funny”) or I_{Kh} (h for “hyperpolarization-activated”), not by Na^+ entering through fast sodium channels. Furthermore, the vagus nerve exerts a profound suppressive influence on the nodal tissues.

Abnormal P Wave. Clinically, abnormalities of the P wave occur with xenobiotics that depress automaticity of the sinus node, causing sinus arrest and nodal or ventricular escape rhythms (β -adrenergic antagonists, calcium channel blockers). The P wave is absent in rhythms with sinus arrest, such as occurs with xenobiotics that produce vagal tone such as cardioactive steroids and cholinergics. A notched P wave suggests delayed conduction across the atrial septum and is characteristic of quinidine poisoning or atrial enlargement (Fig. 16–7). P waves decrease in amplitude as hyperkalemia becomes more severe until they become indistinguishable from the baseline (Chap. 19).

FIGURE 16–7. A notched P wave (arrow) suggests delayed conduction across the atrial septum and is characteristic of quinidine poisoning.

PR Interval

The PR interval is measured from the beginning of the P wave to the beginning of the QRS complex (normal is 120 to 200 msec).

Electrophysiology. Despite rapid conduction by specialized conduction tissue from the SA to the AV node, the AV node delays transmission of the impulse into the ventricles, ostensibly to allow for complete atrial emptying. Thus, the PR interval represents the interval between the onset of atrial depolarization and the onset of ventricular depolarization.

Children usually have more rapid conduction and a shorter PR interval, and older adults generally have a longer PR interval. The segment between the end of the P wave and the beginning of the QRS complex (the PQ segment) reflects atrial contraction and is usually isoelectric. Atrial repolarization coincides with the Q wave, but its ECG findings, or atrial T waves, are obscured by the QRS complex.

Abnormal PR Interval. Xenobiotics that decrease interatrial or AV nodal conduction cause marked lengthening of the PR segment until such conduction completely ceases. At this point, the P wave no longer relates to the QRS complex; this is AV dissociation, or complete heart block. Some xenobiotics suppress AV nodal conduction by blocking calcium channels in nodal cells, as does magnesium, β -adrenergic receptor antagonists, or cholinergics through enhanced vagal tone. Although the therapeutic concentrations of digoxin, as well as early cardioactive steroid poisoning, cause PR prolongation through vagal tone, direct electrophysiologic effects account for the bradycardia of poisoning ([Chap. 65](#) and Antidotes in Depth: A19).

QRS Complex

The QRS complex is the second and typically largest deflection on the ECG. The normal QRS duration in adults varies between 60 and 120 msec. The normal QRS complex axis in the frontal plane lies between -30° and 90° , although most individuals will have an axis between 30° and 75° . This axis will vary with the weight and age of the patient. Alterations in myocardial function may also alter the electrical axis of the heart.

Electrophysiology. The QRS complex reflects the electrical forces generated by ventricular depolarization mediated primarily by Na^+ influx into the myocardial cells. Although under normal conditions both ventricles depolarize nearly simultaneously, the greater mass of the left ventricle causes it to contribute the majority of the electrical forces. The QRS complex is primarily positive in leads I and aV_L on the surface ECG recording because under normal conditions the depolarization vector is directed at 60° and is thus moving toward these leads.

The simultaneous and rapid depolarization of the ventricles results in a very short period of electrical activity recorded on the electrocardiogram. Of course, mechanical systole lasts well past the end of the QRS complex and is maintained by continued depolarization during the plateau phase of the action potential. The return to, and maintenance of, the baseline, or isoelectric potential, simply represents that the entire heart is depolarized and there is no significant net flow of current during this period.

The axis of the terminal 40 msec (0.04 seconds) of the QRS complex represents the late stages of ventricular depolarization and generally follows the direction of the overall axis. This axis is determined by examining the last box (0.04 seconds or 40 msec) of the QRS complex.

Abnormal QRS Complex. In the presence of a bundle-branch block, the two ventricles depolarize sequentially rather than concurrently. Although, conceptually, conduction through either the left or right bundle may be affected, many xenobiotics preferentially affect the right bundle ([Fig. 16–8](#)). The specific reasons for this effect are unclear, but it may be related to differing refractory periods of the tissues. This effect typically results in the left ventricle depolarizing slightly more rapidly than the right. The consequence on the ECG is both a widening of the QRS complex and the appearance of the right ventricular electrical forces that was previously obscured by those of the left ventricle. These changes are typically the result of the effects of a xenobiotic that blocks fast sodium channels. Implicated xenobiotics include cyclic antidepressants,^{10,12} quinidine and other type IA and IC antidysrhythmics²⁰ phenothiazines, amantadine,⁵⁷ diphenhydramine,⁵⁸ carbamazepine,³³ and cocaine.² In the setting of cyclic antidepressant (CA) poisoning, an increased QRS duration has both prognostic and therapeutic value ([Chap. 71](#)).^{7,12,28} In one prospective analysis of ECGs in CA poisoned patients, the maximal limb lead QRS duration was prognostic of seizures (0% if < 100 msec; 30% if greater) and ventricular dysrhythmias (0% if < 160 msec; 50% if greater).¹²

FIGURE 16–8. A 35 year-old woman was found unresponsive in a hallway with an empty bottle of doxepin. Note the progression from (A) a wide QRS interval (108 msec, axis +10), to (B) at >35 min: an RBBB with an axis of -50 and a rightward shift of the terminal 40 msec of the QRS axis, and (C) in the next hour, marked improvement occurred after infusion of hypertonic sodium bicarbonate.

The terminal 40-msec axis of the QRS complex also contains information regarding the likelihood, but not the extent, of poisoning by sodium channel blockers. In a patient poisoned by a sodium channel blocker, the terminal portion of the QRS has a rightward deviation greater than 120° . The common abnormalities include an R wave (positive deflection) in lead aV_R and an S wave (negative deflection) in leads I and aV_L .^{11,36} The combination of a rightward axis shift in the terminal 40 msec of the QRS complex (Fig. 16–9) with a prolonged QT and a sinus tachycardia is highly specific and sensitive for CA poisoning.⁴⁷ Another study suggests that although ECG changes, like a prolonged QRS duration, are better at predicting severe outcomes than the CA concentration, neither is very accurate.⁷ One retrospective study suggests that an absolute height of the terminal portion of aV_R that is greater than 3 mm, predicted seizures or dysrhythmias in CA-poisoned patients.³⁵ However, in infants younger than 6 months, a rightward deviation of the terminal 40-msec QRS axis is physiologic and not predictive of cyclic antidepressant toxicity.¹⁰

FIGURE 16–9. ECG of a patient with a tricyclic antidepressant overdose. The arrows highlight prominent S wave in leads I and aV_L and R wave in aV_R demonstrate the terminal 40-msec rightward axis shift.

An apparent increase in QRS complex duration and morphology, which is an elevation or distortion of the J point called a J wave or an Osborn wave (Fig. 30–3) is a common finding in patients with hypothermia.^{49,63} Hypermagnesemia is also associated with lengthening of the QRS complex duration and a slight narrowing of the QRS complex may occur with hypomagnesemia. Significant hyperkalemia may also cause widening and distortion of the QRS complex.

ST Segment

The ST segment is defined as the distance between the end of the QRS complex and the beginning of the T wave.

Electrophysiology. The ST segment reflects the period of time between depolarization and the start of repolarization, or the plateau phase of the action potential. During this period, no major currents flow within the myocardium, which explains why under normal circumstances the ST segment is isoelectric. Although both the degree of displacement from the baseline and the length of this segment are important, the ST segment duration is usually measured by its effects on the QT duration (see “The QT Interval”).

Abnormal ST Segment. Displacement of the ST segment from its baseline typically characterizes myocardial ischemia or infarction (Fig. 16–10). The subsequent appearance of a Q wave is diagnostic of myocardial infarction. The ECG patterns of these entities reflect the different underlying electrophysiologic states of the heart. Ischemic regions are highly unstable and produce currents of injury because of inadequate repolarization, which is related to lack of energy substrate to power the Na⁺-K⁺-ATPase. Myocardial infarction represents the loss of electrical activity from the necrotic, inactive ventricular tissue, allowing the contralateral ventricular forces to be predominant on the ECG. Patients who are poisoned by xenobiotics that cause vasoconstriction, such as cocaine (Chap. 78), other α -adrenergic agonists, or the ergot alkaloids, are particularly prone to develop focal myocardial ischemia and infarction. The specific ECG manifestations help to identify the region of injury and may, to some extent, be correlated with an arterial flow pattern: inferior (leads II, III, aV_F; right coronary artery); anterior (leads I, aV_L; left anterior descending artery); or lateral (leads aV_L, V_{5–6}; circumflex branch). However, any poisoning that results in profound hypotension or hypoxia may also result in ECG changes of ischemia and injury. In these patients, the injury may be more global, involving more than one arterial distribution. Diffuse myocardial damage may not be identifiable on the ECG because of global, symmetric electrical abnormalities. Under these circumstances, the diagnosis is established by other noninvasive testing, such as by echocardiogram or by finding elevated concentrations of serum markers for myocardial injury such as troponin.

FIGURE 16–10. Leads V₄ to V₆ suggestive of a lateral STEMI are shown from the ECG of a 27 year-old man with substernal chest pain after using crack cocaine.

Many young, healthy patients have ST segment abnormalities that mimic those of myocardial infarction. The most common normal variant is termed “early repolarization” or “J-point elevation,” and is identified as diffusely elevated, upwardly concave ST segments, located in the precordial leads and typically with corresponding T waves of large amplitude (Fig 16–11).¹³ The J point is located at the beginning of the ST segment just after the QRS complex. Because this ECG variant is common in patients with cocaine-associated chest pain (Chap. 78),²⁷ its recognition is critical to instituting appropriate therapy.

FIGURE 16–11. Healthy 34 year-old man whose ECG demonstrates diffusely elevated, upwardly concave ST segments in leads V3 to V5, and T waves of large amplitude suggestive of an “early repolarization” abnormality.

The Brugada electrocardiographic pattern (Fig 16–12) is characterized by terminal positivity of the QRS complex and ST-segment elevation in the right precordial leads. The Brugada pattern is found in some patients with mutations of the gene that codes for the α subunit of the sodium channel. These patients are at risk for sudden death, and a similar ECG pattern

often occurs in patients who are poisoned by sodium-channel–blocking xenobiotics, including CAs, cocaine,²⁶ classes IA (procainamide) class IC (flecainide, encainide) antidysrhythmics.³⁷ In CA-poisoned patients, this pattern is associated with an increased risk of hypotension, but not sudden death or dysrhythmias.⁹ This pattern is also associated with lithium toxicity.

FIGURE 16–12. The Brugada pattern is characterized by terminal positivity of the QRS complex and ST-segment elevation in the right precordial leads and is a similar ECG pattern to that noted in patients poisoned by sodium channel blocking agents such as cyclic antidepressants.⁴ (Used with permission of Vikhyat Bebarta, MD.)

Sagging ST segments, inverted T waves, and normal or shortened QT intervals are characteristic effects of cardioactive steroids, such as digoxin. These repolarization abnormalities are sometimes identified by their similar appearance to “Salvador Dali’s mustache” (Fig. 16–13). As a group, these findings, along with PR prolongation, are commonly described as the “digitalis effect.” They are found in patients with therapeutic drug concentrations and in patients with cardioactive steroid poisoning. As the serum concentration or, more precisely, the tissue concentration increases, clinical and electrocardiographic manifestations of toxicity will appear, which include profound bradycardia or ventricular dysrhythmias.

FIGURE 16–13. Two day-old boy erroneously given 50 µg/kg of digoxin, presented with heart rate 60 beats/min, given digibind. (A) ECG from hospital day 2, before digoxin-specific Fab, and shows “digitalis effect” of the ST segment in leads V1 to V3 (digoxin concentration 4 ng/mL). (B) This finding resolves after the child was switched to amiodarone; notice the QT prolongation.

Changes in the ST segment duration are frequently caused by abnormalities in the serum Ca^{2+} concentration. Hypercalcemia causes shortening of the ST segment through enhanced Ca^{2+} influx during the plateau phase of the cardiac cycle speeding the onset of repolarization. For practical purposes this effect is more commonly identified by reduction of the QT duration (Fig. 16–14). In patients with hypercalcemia, the morphology and duration of the QRS complex and T and P waves remain unchanged. Xenobiotic-induced hypercalcemia may result from exposure to antacids (ie, milk alkali syndrome), diuretics (eg, hydrochlorothiazide), cholecalciferol (vitamin D), vitamin A, and other retinoids. Hypocalcemia causes prolongation of the ST segment and QT interval.

FIGURE 16–14. Electrocardiographic findings associated with changes in serum calcium concentration.

T Wave

The T wave is the third deflection that occurs on the ECG.

Electrophysiology. The T wave represents ventricular repolarization, during which time current is again flowing, although at a cellular level in the opposite direction from that during depolarization. Cardiac repolarization on the larger level generally follows the same pattern as depolarization and thus the deflection is usually in the same direction as the QRS complex. During repolarization, the intracellular potential of the cardiac myocyte becomes more negative as a result of a net loss of positive charge because of the increasing outward flow of potassium ions. As repolarization progresses, the voltage-dependent ion channels “reset” themselves as the intracellular potential falls past their set points. Thus, the initial part of the T wave represents the absolute refractory period of the heart, because at this time there are an insufficient number of reset voltage-dependent calcium channels to allow an impulse to cause a contraction. The latter part of the T wave represents the relative refractory period of the heart, during which time a sufficient number of these calcium channels are available to open with an aberrant depolarization and initiate a contraction.

Abnormal T Wave. Isolated peaked T waves are usually evidence of early hyperkalemia.⁴² Hyperkalemia initially causes tall, tented T waves with normal QRS and QT interval, and a normal P wave (Fig. 16–15). As the serum potassium concentration rises to 6.5 to 8 mEq/L, the P wave diminishes in amplitude and the PR and QRS intervals prolong. Progressive widening of the QRS complex causes it to merge with the ST segment and T wave, forming a “sine wave.” ECG manifestations of hyperkalemia may occur following chronic exposure to numerous xenobiotics, including potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, or potassium supplements (Chap. 19). Fluoride, arsine, and cardioactive steroid poisoning produces acute hyperkalemia, but the latter rarely produces hyperkalemic ECG changes. Peaked T waves also occur following myocardial ischemia and may also be confused with early repolarization effects (see ST Segment). Consequently, the ability to properly identify electrolyte abnormalities by electrocardiography is often limited.

FIGURE 16–15. Electrocardiographic manifestations associated with changes in serum potassium concentration.

Hypokalemia typically reduces the amplitude of the T wave and, ultimately, causes the appearance of prominent U waves (Fig. 16–15). Its effects on the ECG are manifestations of altered myocardial repolarization. Lithium similarly affects myocardial ion fluxes and causes reversible changes on the ECG that may mimic mild hypokalemia, although documentation of low cellular potassium concentrations is lacking. Patients chronically poisoned with lithium have more T-wave abnormalities (typically flattening) than do those who are poisoned acutely, but these abnormalities are rarely of clinical significance.⁶¹

QT Interval

The QT is measured from the beginning of the QRS complex to the end of the T wave. The QT interval normally varies because of biologic diurnal effects and autonomic tone, technical issues with the environment or with processing and acquiring the ECG, and observer variability.^{3,43,44} The bipolar limb lead with the largest T wave should therefore be used for this measurement.

The QT interval is normally prolonged at slower heart rates and shortens as the heart rate increases. This is especially important since many of the xenobiotics that affect the QT interval also affect the heart rate. As the normal QT varies also with the heart rate, numerous formulas and tables are available to obtain the corrected QT, known as the QTc.²⁵ Using the QTc allows the determination of the appropriateness of the QT independent of the heart rate.

With a rate of 50 to 90 beats/min, the commonly used Bazett formula ($QTc \text{ (msec)} = QT \text{ (msec)} / \sqrt{RR \text{ interval (sec)}}$) is adequate for determining a rate corrected QT interval (QTc). If the RR interval is calculated as 60/beats/min, 99% of men have a QTc < 450 msec and 99% of women have a QTc < 460 msec.⁴⁵ A QTc interval > 500 msec weakly correlates with an increased risk of developing ventricular dysrhythmias. However, at higher heart rates, a normal patient will have an

inaccurately calculated “prolonged” QTc interval using the Bazett formula. Studies suggest that medications such as bupropion prolong the QT interval when the “increase” in the QTc may be only a result of the increased heart rate.²⁹ A variety of formulas and corrections are proposed to attempt to identify normal QT intervals on ECGs at higher heart rates,^{6,18,38} including the Fridericia formula ($QTc = QT / \sqrt[3]{RR \text{ interval (sec)}}$) and the Framingham linear regression analysis ($QT_{LC} = QT + 0.154 (1 - RR)$).⁵⁶ Which correction formula is optimal remains unknown, and the FDA requests that “presentation of data with a Fridericia correction is likely to be appropriate in most situations, but other methods could be more appropriate” when performing a “thorough QT study” for any drug with proarrhythmic potential.²³ A recent QT nomogram that plots QT interval duration versus heart rate may better predict the risk for lethal dysrhythmia.¹⁷

With slow heart rates, a prominent U wave can obscure the terminal portion of the T wave and with fast heart rates the subsequent P wave can obscure the terminal portion of the T wave. In these patients the QTc should be estimated by following the downslope of the T wave. The QTc is often measured to approximate repolarization, although this is not fully appropriate because alterations in depolarization may affect it.

QT interval measurements from the computerized ECG algorithms are less accurate than careful manual determinations of the interval.³¹ In August 2000, a panel of experts convened to address these issues and suggested that the QT interval should be measured manually in one of the limb leads that best shows the end T wave; the QT interval should be measured and averaged over 3 to 5 beats; and large U waves should be included in the QT interval measurement if they merge into the T wave and obscure the end of the T wave.⁴ However, a subsequent study of 334 health care professionals found that only 60% of the physicians were able to correctly measure a sample QT interval on the survey, although nearly all indicated correctly that the measurement should be from the beginning of the QRS to the end of the T wave.³⁴

Electrophysiology. The QT represents the entire duration of ventricular systole and thus is comprised of several electrophysiologic periods. Prolongation of the QT interval generally corresponds to an increase in the duration of phase 2 or 3 of the action potential. Although as noted above, depolarization abnormalities can affect the QT. These are uncommon, and the plateau phase and repolarization are primarily reflected by the QT. Variations in the speed of the paper,²¹ T-wave morphology, irregular baseline, and the presence of U waves may make this determination difficult.⁴

Abnormal QT Interval. A prolonged QT reflects an increase in the time period that the heart is “vulnerable” to the initiation of ventricular dysrhythmias (Table 16–1, Fig. 16–16). This occurs because although some myocardial fibers are refractory during this time period, others are not (ie, relative refractory period). Early afterdepolarizations (EADs) may occur in patients with lengthened repolarization time (Table 16–2). An EAD occurs when a myocardial cell spontaneously depolarizes before its repolarization is complete (Fig. 16–17). If this depolarization is of sufficient magnitude, it may capture and initiate a premature ventricular contraction, which itself may initiate ventricular tachycardia, ventricular fibrillation, or torsade de pointes. There are two types of EADs based on whether they occur during phase 2 (type 1) or phase 3 (type 2) of the cardiac action potential. The ionic basis of EADs is unclear, but may be via the L-type calcium channel; EADs are suppressed by magnesium.⁸

TABLE 16–1. Xenobiotic Causes of Long QT^a

Antidysrhythmics

Classes IA, IC, and III antidysrhythmics

Antifungals: itraconazole, ketoconazole

Antihistamines: diphenhydramine

Antihypertensives: angiotensin converting enzyme inhibitors

Antimicrobials: amantadine, chloroquine, halofantrine, fluoroquinolones, macrolides, pentamidine, trimethoprim-sulfamethoxazole

Antiretrovirals: ritonavir-boosted saquinavir

Electrolyte disturbances

Hypocalcemia: fluoride oxalate (eg, ethylene glycol)

Hypokalemia: soluble barium

Other: arsenic trioxide, cocaine, foscarnet, methadone, organic phosphorus insecticides, tacrolimus

Psychotropics: atypical antipsychotics, citalopram, cyclic antidepressants, droperidol, haloperidol, pimozide, phenothiazines, quetiapine, venlafaxine, ziprasidone

FIGURE 16–16. 33 year-old woman who ingested excessive methadone along with ethanol 3 hours before admission. Her ECG shows a sinus bradycardia and QT prolongation.

TABLE 16–2. Electrophysiologic Basis for Delayed Afterdepolarization and Early Afterdepolarization

	<i>Phase of Action Potential Affected by Depolarization</i>	<i>Clinical Effect</i>	<i>Mechanism</i>
Delayed after-depolarization	Phase 4	Cardioactive steroid–induced dysrhythmias	↑ Intracellular Ca^{2+} → Activation of a nonselective cation channel or Na^{+} - Ca^{2+} exchanger → Transient inward current carried mostly by Na^{+} ions
Early after-depolarization	Phase 2 Phase 3	↑ Repolarization time Long QT syndrome (hereditary and acquired) Drug-induced torsade de pointes, ventricular tachycardia	Multifactorial (K^{+} , Na^{+} - K^{+} , Ca^{2+} , Na^{+} currents) Suppressed by magnesium

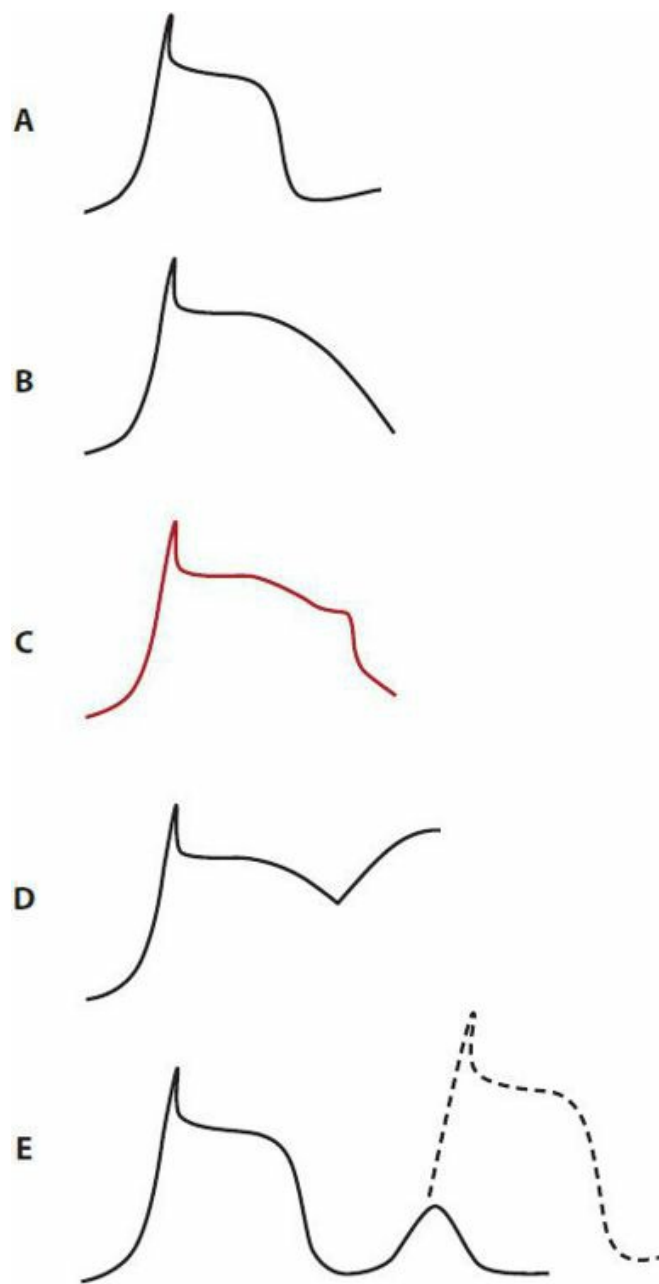

FIGURE 16–17. Afterdepolarization. (A) The normal action potential. (B) Prolonged duration action potential. (C) Prolonged duration action potential with an early after depolarization (EAD) occurring during the downslope of phase 3 of the action potential. (D) Early afterdepolarization that reaches the depolarization threshold and initiates another depolarization, or a triggered beat. (E) Delayed afterdepolarization, which occurs after repolarization is complete.

Xenobiotics that cause sodium channel blockade ([Chaps. 67 and 71](#)) prolong the QT duration by slowing cellular depolarization during phase 0. Thus, the QT duration increases because of a prolongation of the QRS complex duration, and the ST segment duration remains near normal. Xenobiotics that cause potassium channel blockade similarly prolong the QT, but through prolongation of the plateau and repolarization phases. This specifically prolongs the ST segment duration. Although at a cellular level these xenobiotics are antidysrhythmic, the multicellular effects may be prodysrhythmic. The highly selective serotonin reuptake inhibitor citalopram causes QT prolongation due to the sodium and calcium channel blocking effects of its metabolite didesmethyl-citalopram. In a recent large retrospective cohort study, users of both typical antipsychotics (thioridazine and haloperidol) and atypical antipsychotics (clozapine, quetiapine, olanzapine, risperidone) had a risk of sudden cardiac death that was twice that of non-users of antipsychotics. Xenobiotic-induced QT prolongation and the subsequent risk of dysrhythmias is the postulated etiology.⁵² Hypocalcemia may produce a prolonged QT interval, and is caused by a number of xenobiotics, including fluoride, calcitonin, ethylene glycol, phosphates, and mithramycin ([Table 19–9](#)). Hypokalemia alone does not usually prolong the QT. Arsenic poisoning may cause prolongation of the QT and result in torsade de pointes. The mechanism is unknown, although increases in cardiac Ca^{2+} currents and reduction in surface expression of the cardiac potassium channel HERG are postulated.²²

QT Dispersion. The QT interval may vary in duration from lead to lead, reflecting a dispersion or variability in regional myocardial repolarization. Both QT and QTc dispersion can be calculated. The normal QT and QTc interval dispersions are 30 to 50 msec and 40 to 60 msec, respectively. The conduction characteristics vary regionally throughout the heart. For example, the subendocardial cells have a longer action potential duration than do epicardial cells; this is called dispersion of repolarization and is normal. This is important to allow the heart to contract and relax in an

appropriate manner even though the impulse takes time to travel through the full thickness of the myocardial wall, from endocardium to epicardium. The subpopulations of the various ion channels (primarily potassium channels in the setting of repolarization) differ in character and density and account for this variation.⁴⁶ Ischemia and xenobiotics preferentially affect certain layers of the myocardium and alter, generally increasing, the regional heterogeneity of repolarization. M cells, located in the mid myocardium, are very sensitive to the effects of xenobiotics and may increase the repolarization heterogeneity.³⁰ This is reflected on the ECG as an increase in QT dispersion and a prolongation of the vulnerable period. This prolonged vulnerable phase is associated with occurrences of ventricular dysrhythmias. A measured QT dispersion greater than 80 msec after myocardial infarction was associated with VT with a sensitivity rate of 73% and a specificity rate of 86%.⁵⁰ This heterogeneity is also correlated with both the efficacy and prodysrhythmic potential of therapy.⁵⁹ However, the overall assessment of QT dispersion (from a standard 12-lead ECG) has not gained popularity as a useful clinical tool.

U Wave

The U wave is a small deflection that occurs after the T wave and usually with a similar orientation. Distinguishing a U wave from a notched T wave is difficult. The apices of a notched T wave are usually < 150 msec apart, and the peaks of a TU complex are > 150 msec apart.

Electrophysiology. U waves occur when there is fluctuation in the membrane potential following myocardial repolarization. Prominent U waves are generally representative of an underlying electrophysiologic abnormality, although they may be physiologic. Physiologic U waves may be caused by repolarization of the Purkinje fibers, or they may correspond to late repolarization of myocardial cells in the mid-myocardium, and are implicated in the initiation of cardiac dysrhythmias.⁴

Abnormal U Wave. Abnormal U waves are typically caused by spontaneous afterdepolarization of membrane potential that occurs in situations where repolarization is prolonged (Fig. 16–17). An EAD occurs in situations where the prolonged repolarization period allows calcium channels (which are both time and voltage dependent) to close and spontaneously reopen because they may close at a membrane potential that is above their threshold potential for opening. M cells in the mid-myocardium are particularly sensitive to xenobiotics causing prolonged repolarization and EADs. In this situation, the opening of the calcium channels produces a slight membrane depolarization that is identified as a U wave. A delayed afterdepolarization (DAD) is noted during phase 4 of the action potential. It occurs when the myocyte is overloaded with Ca^{2+} , as in the setting of cardioactive steroid toxicity. The excess intracellular Ca^{2+} can trigger the ryanodine receptors on the myocyte sarcoplasmic reticulum to release Ca^{2+} , causing slight depolarization that is erroneously recognized as a U wave. If the afterdepolarization is of sufficient magnitude to reach threshold, the cell may depolarize and initiate a premature ventricular contraction. Transient U-wave inversion can also be caused by myocardial ischemia or left ventricular overload as occurs in systemic hypertension.

Abnormal QU Interval. The QU interval is the distance between the end of the Q wave and the end of the U wave. Differentiation between the QU and the QT intervals is difficult if the T and U waves are superimposed. When hypomagnesemia coexists with hypokalemia, as is usually the case, QU prolongation and torsade de pointes may occur.⁶²

CARDIAC DYSRHYTHMIAS AND CONDUCTION ABNORMALITIES

Xenobiotics may produce adverse effects on the electrical activity of the heart, often by acting directly on the myocardial cells. Because metabolic abnormalities (especially acidemia, hypotension, hypoxia, and electrolyte abnormalities) can further exacerbate the toxicity, or can actually be the sole cause of the cardiovascular abnormalities, correction of metabolic abnormalities must be a high priority in the treatment of patients with cardiovascular manifestations of poisoning. The terminal phase of any serious poisoning may include nonspecific hemodynamic abnormalities and cardiac dysrhythmias. However, many xenobiotics directly or primarily affect cardiac rhythm or conduction, often through effects on the cardiac ion channels.

The distinction between xenobiotics that cause a rapid rate and those that cause a slow rate on the ECG is somewhat artificial, because many can do both. For example, patients poisoned by CAs almost always develop sinus tachycardia, but most who die will have a wide complex bradycardia immediately prior to death. In either case, abnormalities in the pattern or rate on the ECG can provide the clinician with immediate information about a patient's cardiovascular status. ECG disturbances in many poisoned patients may be categorized in more than one manner (abnormal pattern, fast rate, slow rate). In any case, when ECG abnormalities are detected, appropriate interpretation, evaluation, and therapy must be rapidly performed.

Xenobiotics that directly cause dysrhythmias or cardiac conduction abnormalities usually affect the myocardial cell membrane. Other xenobiotics that modify ion channels may alter the transmembrane potentials within myocytes and may result in the spontaneous generation of an abnormal rhythm.

Mechanisms of Dysrhythmia Initiation and Propagation

Dysrhythmias can be related to one or more of three mechanisms: abnormal spontaneous depolarization (enhanced automaticity), afterdepolarization (triggered automaticity), and reentry.⁴⁶ In normal myocardium, spontaneous, phase 4 depolarization occurs most rapidly in the sinus node, the normal pacemaker for the heart. Speeding or slowing the rate of phase 4 depolarization of the pacemaker cell results in sinus tachycardia or sinus bradycardia, respectively. However, xenobiotics can also speed the depolarization of other myocardial cells that have pacemaker potential allowing them to overtake the sinus node as the primary pacemaker. This mechanism, called increased automaticity, accounts for many of the dysrhythmias that occur with cardioactive steroid and β -adrenergic agonist poisoning.

Afterdepolarizations, mentioned above, typically occur during phase 3 or 4 of the action potential, and may reach the threshold potential, causing the fast sodium channels to open and initiate an action potential. EADs account for the “trigger beats” that initiate episodes of VT, commonly torsade de pointes (TdP), when the action potential is prolonged, as discussed below. DADs are typically associated with cardioactive steroid toxicity⁴⁶ and excessive sympathetic stimulation.

Most afterdepolarizations do not propagate rapidly throughout the myocardium and do not generate ectopic beats. However, because the normal dispersion of repolarization is increased by certain xenobiotics, ectopic beats (eg, atrial premature contraction or ventricular premature contraction) may propagate abnormally within the myocardium. Ectopy is the ECG manifestation of myocardial depolarization initiated from a site other than the sinus node. Ectopy may be lifesaving under circumstances in which the atrial rhythm cannot be conducted to the ventricles (ie, “escape rhythm”), as during high-degree AV blockade induced by cardioactive steroids (Chap. 65). Alternatively, ectopy may lead to dramatic alterations in the physiologic function of the heart or deteriorate into lethal ventricular dysrhythmias.

Occasionally, because of the altered regional repolarization (ie, increased dispersion of repolarization), an impulse may reach a branch point with a partial block (ie, relatively refractory) to conduction in one of the branches (Fig. 16–18). The impulse is carried through only one of the branches and then spreads through the myocardial cells. After a short delay, the impulse reaches the distal end of the previously blocked pathway. By this time, the region is no longer refractory and conducts the impulse in a retrograde fashion. The impulse may continue in a continuous loop circuit, depolarizing the heart with each passage; this process is called reentry. Reentrant mechanisms appear to be responsible for the majority of the malignant tachydysrhythmias attributable to poisoning.

FIGURE 16–18. Mechanism of reentrant dysrhythmias. An impulse traveling down a conduction pathway reaches a branch point with one branch refractory (C). The impulse is conducted down branch A and spreads through the myocardium eventually to reach B, the distal end of the originally refractory branch. However, branch C is no longer refractory, and the impulse is conducted retrograde up through branch C, again to be conducted down branch A. The myocardium is depolarized during each loop around the circuit as the impulse spreads from the distal end of branch A to the rest of the heart.

Tachydysrhythmias

Both supraventricular and ventricular tachydysrhythmias can occur in poisoned patients (Table 16–3). Sinus tachycardia is the most common rhythm disturbance that occurs in poisoned patients. Parasympatholytic xenobiotics, such as atropine, raise the heart rate to its innate rate by eliminating the inhibitory tonic vagal influence. However, more rapid rates require direct myocardial stimulatory effects, generally mediated by β -adrenergic agonism. For example, catecholamine excess, as occurs in patients with cocaine use, psychomotor agitation, or fever, may cause sinus tachycardia with rates faster than 150 beats/min. Ventricular dysrhythmias frequently accompany hypotension, hypoxia, acidemia, electrolyte abnormalities, and other metabolic derangements that may be present in poisoned patients or may be a direct effect of the xenobiotic.

TABLE 16–3. Xenobiotics Causing Ventricular and Supraventricular Tachydysrhythmias

Amantadine

Antidysrhythmics: classes IA, IC, and III ([Table 16–2](#))

Anticholinergics

Antihistamines

Antipsychotics

Botanicals (Diverse) ([Chap. 121](#))

Carbamazepine

Cardioactive steroids

Chloroquine and quinine

Cyclic antidepressants

Cyclobenzaprine

Hydrocarbons and solvents

Halogenated hydrocarbons

Inhalational anesthetics

Jellyfish venom

Metal salts

Arsenic

Lithium

Magnesium

Potassium

Pentamidine

Phenothiazines

Phosphodiesterase inhibitors (eg, methylxanthines)

Propoxyphene

Sedative-hypnotics

Chloral hydrate

Ethanol (“holiday heart”)

Sympathomimetics (eg, cocaine)

Thyroid hormone

The intrinsic pacemaker cells of the heart undergo spontaneous depolarization and reach threshold at a predictable rate. Under normal circumstances the sinus node is the most rapidly firing pacemaker cell of the heart; and as a result it controls the heart rate. Other potential pacemakers exist in the heart, but their rate of spontaneous depolarization is considerably slower than that of the sinus node. Thus, they are reset during depolarization of the myocardium and they never spontaneously reach threshold. Xenobiotics, such as sympathomimetics, which speed the rate of rise of phase 4, or diastolic depolarization, speed the rate of firing of the pacemaker cells. As long as the sinus node is preferentially affected, it

maintains the pacemaker activity of the heart. If the firing rate of another intrinsic pacemaker exceeds that of the sinus node, ectopic rhythms may develop.

Certain xenobiotics are highly associated with ventricular tachydysrhythmias following poisoning. Those that increase the adrenergic tone on the heart, either directly, or indirectly, may cause ventricular dysrhythmias. Whether a result of excessive circulating catecholamines observed with cocaine and sympathomimetics, myocardial sensitization secondary to halogenated hydrocarbons or thyroid hormone, or increased second messenger activity secondary to methylxanthines, the extreme inotropic and chronotropic effects cause dysrhythmias. Altered repolarization, increased intracellular Ca^{2+} concentrations, or myocardial ischemia can cause dysrhythmias. Additionally, xenobiotics that produce focal myocardial ischemia, such as cocaine, ephedrine, or ergots can lead to malignant ventricular dysrhythmias. Finally, an uncommon cause of xenobiotic-induced ventricular dysrhythmias is persistent activation of sodium channels, such as following aconitine poisoning. Although not all wide QRS complex tachydysrhythmias are ventricular in origin, making this assumption is generally considered to be prudent. For example, in a patient poisoned with cyclic antidepressants or cocaine, the differentiation of aberrantly conducted sinus tachycardia (common) from ventricular tachycardia (rare) is important, but difficult. Although guidelines for determining the origin of a wide complex tachydysrhythmia exist,¹⁴ they are imperfect, difficult to apply, and unstudied in poisoned patients.

Bidirectional ventricular tachycardia is associated with severe cardioactive steroid toxicity and results from alterations of intraventricular conduction, junctional tachycardia with aberrant intraventricular conduction, or, on rare occasions, alternating ventricular pacemakers (Fig. 16–19). Aconitine, usually obtained from traditional Chinese or other alternative therapies that contain plants of the *Aconitum* spp (such as *Aconitum napellus* (monkshood), may cause bidirectional ventricular tachycardia (Chaps. 45 and 121).

FIGURE 16–19. Digoxin-induced bidirectional ventricular tachycardia. The ECG demonstrates the alternating QRS axis characteristic of bidirectional ventricular tachycardia and is nearly pathognomonic for cardioactive steroid poisoning. The 89 year-old patient's serum digoxin concentration was 4.0 ng/mL. (Used with permission of Ruben Olmedo, MD, Mount Sinai School of Medicine.)

Tachydysrhythmia Associated with a Prolonged QT Interval: Torsade de Pointes

Xenobiotics that alter myocardial repolarization and prolong the QT interval predispose to the development of afterdepolarization-induced contractions during the relative refractory period (R on T phenomena), which may initiate ventricular tachycardia. If TdP is noted this is undoubtedly the mechanism, and the QT interval should be carefully assessed and appropriate treatment initiated (Fig. 16–20).

FIGURE 16–20. Torsade de pointes in a patient who ingested an unknown amount of thioridazine.

Ventricular tachycardia, including TdP, is usually a reentrant-type rhythm. The presence of a prolonged QT interval on the ECG may indicate the possible existence of conditions within the myocardium that favor occurrence of reentry dysrhythmias, as discussed above. The long action potential duration resulting from prolongation in the duration of phase 2 or 3 increases the occurrence of EADs. These, in combination with an increased dispersion of repolarization, increase the risk for reentrant dysrhythmias, particularly TdP.

Many xenobiotics may also interact with cardiac membrane ion channels and increase the risk of TdP. Most of these xenobiotics interact with the HERG-encoded subunit of the potassium channel to reduce the current through the I_{K_r} channel and prolong the action potential duration. The HERG subunit of the channel is particularly susceptible to xenobiotic interactions because of the larger inner cavity with aromatic binding domains.^{53,54,60} Acquired QT interval prolongation and TdP from xenobiotics occur most often with class IA and IC antidysrhythmics, the cyclic antidepressants, and the antipsychotics. Although class Ic antidysrhythmics (such as encainide and flecainide) cause greater QT prolongation, class IA agents (such as quinidine and procainamide) are responsible for more reported cases. This is probably a result of the relatively infrequent use of the class Ic antidysrhythmics, due paradoxically, to concerns about the higher risk of prodysrhythmic effects. Class IB agents, such as lidocaine, have no significant effect on potassium channels and the QT interval, and do not cause TdP. Acquired QT interval prolongation and TdP also commonly result from metabolic and electrolyte abnormalities, particularly hypocalcemia, hypomagnesemia, and hypokalemia (Chaps. 19 and 64).

Bradydysrhythmias

Bradycardia, heart block, and asystole are the terminal events following fatal ingestions of many xenobiotics, but some xenobiotics tend to cause sinus bradycardia (Table 17–2) and conduction abnormalities (Table 16–4) early in the course of toxicity. Sinus bradycardia with an otherwise normal electrocardiogram is characteristic of xenobiotics that reduce central nervous system outflow (Chap. 17). Xenobiotics that cause CNS sedation, such as the sedative-hypnotics, most opioids, and α_2 -adrenergic receptor agonist (“centrally acting”) antihypertensive drugs, will usually decrease sympathetic outflow to the heart and produce a heart rate in the range of 40 to 60 beats/min. Differentiating among these xenobiotics is not possible based on ECG criteria alone. Xenobiotics that directly affect ion flux across myocardial cell membranes cause abnormalities in AV nodal conduction. Calcium channel blockers, β -adrenergic antagonists, and cardioactive steroids (Chaps. 61, 62, and 65) are the leading causes of sinus bradycardia and conduction disturbances. Indirect metabolic effects may also be contributory, such as severe hyperkalemia (which may accompany any acidosis), which results in a wide complex, sinusoidal bradycardic rhythm.

TABLE 16–4. Xenobiotics Causing Conduction Abnormalities and/or Heart Block

α_1 and α_2 -adrenergic agonists
β_1 and β_2 -adrenergic antagonists
Amantadine
Anesthetics (local)
Antidepressants
Antidysrhythmics (classes I and III)
Antihistamines
Antimicrobials

Chloroquine and quinine

Macrolides

Quinolones

Antipsychotics

Atypical antipsychotics (quetiapine, olanzapine, risperidone)

Droperidol

Haloperidol

Phenothiazines

Calcium channel blockers

Carbamazepine

Cardioactive steroids

Cholinergics

Cocaine

Cyclic antidepressants

Cyclobenzaprine

Electrolytes

Potassium

Magnesium

Metal salts

Arsenic

Methadone

Pentamidine

Propoxyphene

Xenobiotics that have direct depressant effects on the cardiac pacemaker are most likely to produce bradycardia. The ECG manifestations of calcium channel blocker and β -adrenergic antagonist overdoses are difficult to distinguish. In general, both decrease dromotropy (conduction), although the specific pharmacologic actions of the drugs differ even within the class. For example, most members of the dihydropyridine subclass of calcium channel blockers do not have any antidromotropic effect, whereas verapamil and diltiazem routinely produce PR prolongation. Similarly, while most β -adrenergic antagonists produce sinus bradycardia and first-degree heart block, certain members of this group, such as propranolol, may prolong the QRS complex through their sodium channel blocking abilities ([Chap. 62](#)). Others, such as sotalol, which has properties of the class III antidysrhythmics, blocks myocardial potassium channels and prolongs the QT interval duration. Bradycardia associated with cardioactive steroids is typically accompanied by electrocardiographic signs of “digitalis effect,” including PR prolongation and ST segment depression ([Chap. 65](#)).

CONDUCTION ABNORMALITIES AND AV NODAL BLOCK

The cardiac toxicity of some xenobiotics results from their effects on the propagation of the electrical impulse through the conduction system of the heart. The ECG abnormalities produced may be a result of effects on the AV node, producing first-, second-, or third-degree (complete) heart block, or on the His-Purkinje system, producing intraventricular conduction delays such as bundle-branch blocks. The effects of xenobiotics on myocardial conduction are often mediated through

interactions with the sodium or potassium membrane channels. For example, xenobiotics that affect the fast inward I_{Na} currents (such as the type I antidysrhythmics and cyclic antidepressants) prolong the action potential duration, slow ventricular myocyte depolarization, and slow intraventricular conduction. This produces widening of the QRS complex and prolongation of the QT interval on the ECG. [Table 16–4](#) lists some of the xenobiotics that cause conduction abnormalities. Many of the antidysrhythmics derive their clinical benefit from their ability to alter sodium and potassium channel function and slow conduction through the myocardium. Xenobiotics that depress phase 0 (the inward I_{Na} currents) produce slowing of conduction and widening of the QRS complex. Xenobiotics that prolong depolarization and repolarization (phase 2 or 3 of the action potential) produce prolongation of the QT interval on the ECG. The classes of the antidysrhythmics, their effects on the ion channels and on the action potential, and the resulting ECG abnormalities, are shown in [Table 16–5](#) and discussed in detail in [Chaps. 16](#) and [64](#).

TABLE 16–5. Classes of Antidysrhythmics

Class	Pharmacologic Blockade			Prolongation of ECG Intervals			Examples
	Sodium Channels	Potassium Channels	Calcium Channels	PR	QRS	QT	
Sodium channel blockers							
IA	+++ / ++++	++	0	±	↑	↑	Disopyramide Procainamide Quinidine
IB	+ / ++	±	0	±	±	±	Lidocaine Phenytoin Mexiletine Tocainide
IC	+++	+++ / ++++	0	↑	↑	↑↑	Encainide Flecainide Propafenone Moricizine
β-Adrenergic antagonists							
II	0	0	+(indirect)	↑	±	±	Atenolol Esmolol Metoprolol Propranolol Timolol
Potassium channel blockers							
III	+	++	0	↑	±	↑	Amiodarone Dofetilide Dronedarone Sotalol Ibutilide*
Calcium channel blockers							
IV	0	0	+++	↑	±	±	Verapamil Diltiazem

+ = Mild blockade; ++ = moderate blockade; +++ = marked blockade; ↑ = increases; ± = no significant effect

*Ibutilide activates a slow inward sodium channel rather than blocking outward potassium currents, but it is classified as class III because of its increased action potential duration and atrial and ventricular refractoriness, which are typical of class III antidysrhythmics.

PEDIATRIC ECG

Normal Pediatric ECG

The normal pediatric ECG differs in many ways from the normal adult ECG. The resting heart rate of infants and children is substantially faster than that of adults and, in general, conduction is faster. In a term infant, the right ventricle is substantially larger than the left, and the ECG demonstrates prominent R waves in the right precordium and deep S waves in the left lateral precordium.⁴⁸ This may be misinterpreted as cyclic antidepressant toxicity.¹⁰ An adult ratio of left to right ventricular size is usually reached by the age of 6 months. In infants, Q waves commonly exist in the inferior and lateral precordial leads, but are abnormal in leads I and aV_L. The T waves are the most notable difference between pediatric and adult ECGs. The T waves in the right precordial leads in children are deeply inverted until 7 years and sometimes older, in which case it is called a persistent juvenile T-wave pattern.

Abnormal Pediatric ECG

Although congenital heart disease is the most common cause of ECG abnormalities in children, electrolyte disorders and xenobiotics may also cause changes in electrophysiology that are reflected on the ECG. Abnormalities that are useful markers on the adult ECG may not always be as useful in children. For example, in older children, a retrospective chart review of 37 children diagnosed with tricyclic antidepressant overdose and 35 controls (<11 years) found interpatient variability, unrelated to age, so great that a rightward deviation of the terminal 40-msec QRS axis could not distinguish between poisoned and healthy children.¹⁰

SUMMARY

- Electrocardiography is one of the few widely available diagnostic procedures that reveals immediate, useful clinical information.
- A thorough mechanistic understanding of the etiologies of the various waves and intervals may help provide an early clue to the etiology of a patient's toxicity.
- QRS prolongation is characteristic of sodium channel blockade.
- QT prolongation is characteristic of potassium channel blockade.

17 CARDIOLOGIC PRINCIPLES II: HEMODYNAMICS

Robert A. Hessler

Adequate tissue perfusion depends on maintenance of volume status, vascular resistance, cardiac contractility, and cardiac rhythm. All of these components of the hemodynamic system are vulnerable to the effects of xenobiotics. Cardiovascular toxicity may therefore be manifested by the development of hemodynamic instability, heart failure, cardiac conduction abnormalities, or dysrhythmias. The presence of a specific pattern of cardiovascular anomalies (toxicologic syndrome or “toxidrome”) may suggest a particular class or type of xenobiotic.

In addition, an alteration in hemodynamic functioning may be the indirect result of metabolic abnormalities. Poisoning with a xenobiotic may lead to development of acid base disturbances, hypoxia, or electrolyte abnormalities with secondary hemodynamic changes. In these patients, supportive care with ventilation, oxygenation, and fluid and electrolyte repletion may improve the cardiovascular status. For example, salicylates may cause hypotension and cardiovascular collapse. These hemodynamic effects are primarily due to the systemic acidosis and electrolyte disturbances ([Chap. 39](#)).

PHYSIOLOGY OF THE HEMODYNAMIC SYSTEM

Maintaining cardiac contractility, heart rate and rhythm, and vascular resistance requires complex modulation of the cardiac and vascular systems. Xenobiotics can cause hemodynamic abnormalities as a result of direct effects on the myocardial cells, on the cardiac conduction system, or on the arteriolar smooth muscle cells. These effects are frequently mediated by interactions with cellular ion channels or cell membrane neurohormonal receptors. These complex cellular systems provide multiple sites for xenobiotics to demonstrate their toxicologic effects. Xenobiotics and xenobiotic metabolites can interact with the cellular receptors, intracellular signal mechanisms, or with the effector enzymes and intracellular organelles.

Toxic effects of xenobiotics can obviously be due to direct poisoning from excessive amounts of a xenobiotic that follow an overdose. Additionally, slower accumulation of the xenobiotic or active metabolites (due to alterations in metabolism) can also lead to adverse effects. However, the toxic effects of a xenobiotic may be due largely to the properties and characteristics of the host subject. Underlying medical conditions, presence of other xenobiotics, electrolyte abnormalities, concurrent acid-base, and hydration status can all contribute to the potential adverse hemodynamic effects of a xenobiotic. Even with a usually non-harmful concentration of a xenobiotic, hemodynamic toxicity may occur due entirely to underlying genetic differences in the cellular receptors or the intracellular signal transducers in the particular patient.

This complex interaction between the xenobiotic and patient’s physiology and genetic diversity is exemplified by the cardiac disorder, Brugada syndrome. This congenital cardiac channelopathy ([Chaps. 16 and 64](#)) predisposes to sudden cardiac death due to polymorphic ventricular tachycardia or ventricular fibrillation. Brugada syndrome is characterized by an atypical right bundle branch pattern with a characteristic cove-shaped ST segment elevation in leads V1 to V3 of the electrocardiogram (ECG) in the absence or structural heart disease, ischemia, or electrolyte disturbances).^{9,86} This typical type 1 Brugada ECG pattern is shown in [Fig. 16–12](#). However, this distinctive ECG pattern may be concealed²⁶ and only unmasked by sleep, fever, bradycardia, or by xenobiotics such as vagotonic medications or class I antidysrhythmics (sodium channel blocking agents).^{3,58} The reason for this variable and dynamic response to xenobiotics is the heterogeneous genetic basis of the disorder. Mutations in 10 different genes have been linked to the Brugada syndrome; more than 300 different mutations have been identified in the SCN5A gene alone (which encodes the α subunit of the cardiac sodium channel). Brugada syndrome is also associated with mutations in other cardiac ion channels and with mutations of the glycerol-3-phosphate 1-like (GDP1L) gene, which interacts with the cardiac sodium channel subunits at the cell membrane.⁴ The complexity of the potential xenobiotic interactions and variable potential for toxicity has led to the establishment of a Web page (www.brugadadrugs.org) established by the Netherlands Heart Foundation and the University of Amsterdam to provide up-to-date classification of xenobiotics into those to avoid, those to preferably avoid, and those to potential use for treatment.^{58,59}

Autonomic Nervous System and Hemodynamics

In addition to the voltage-dependent ion channels, the cell membrane contains channels that open in response to receptor

binding of neurotransmitters or neurohormones.⁶⁰⁻⁶² The hemodynamic effects of many xenobiotics are mediated by interactions with membrane receptors and by changes in the autonomic nervous system. The autonomic nervous system is functionally divided into the sympathetic (ie, adrenergic) and parasympathetic (ie, cholinergic) systems. The two systems, which share certain common features, function semi-independently of each other. Through complex feedback, the two systems provide the balance needed for existence under changing external conditions.

The sympathetic nervous system is primarily responsible for the maintenance of arteriolar tone and cardiac function. Norepinephrine is the primary postganglionic neurotransmitter of the sympathetic nervous system. On release into the synapse, norepinephrine binds to the postsynaptic adrenergic receptors to elicit an effect by the postsynaptic cell.

ADRENERGIC RECEPTORS

Cellular Physiology of Adrenergic Receptors

The effects of adrenergic xenobiotics on the cell are primarily mediated through a secondary messenger system of cyclic adenosine monophosphate (cAMP). The intracellular cAMP concentration is regulated by the membrane interaction of three components: the adrenergic receptor, a “G-protein” complex, and adenyl cyclase, the enzyme that synthesizes cAMP in the cell.^{10,22,78,79} These receptors are described in detail in Chap. 14.

The G protein serves as a “signal transducer” between the receptor molecule in the cell membrane and the effector enzyme, adenyl cyclase, in the cytosol. The G proteins consist of three subunits: α , β , and γ .^{14,52,53} The α subunit of the G protein complex binds to the adrenergic receptor in the cell membrane and to the adenyl cyclase enzyme. The G protein complex exists in several isomeric forms, depending on their interactions with the adenyl cyclase enzyme. These forms, G_s , G_i , and G_q have different functions in the regulation of cellular activity. The G_s protein complexes contain α_s subunits that stimulate adenyl cyclase when “activated” by adrenergic receptor interaction. These G_s complexes are primarily responsible for the stimulatory activity of β -adrenergic agonist agents. β_1 - and β_2 -adrenergic receptors interact primarily with β_s subunits in stimulatory G_s protein complexes. The α_i subunits of G_s proteins inhibit the activity of adenyl cyclase. Some β_2 -adrenergic receptors and the α_2 -adrenergic receptors interact with inhibitory G_i proteins to decrease the activity of adenyl cyclase. A third form, G_q , interacts with the α_1 -adrenergic receptors, but does not interact directly with adenyl cyclase. Instead, the G_q interacts with phospholipase C to mediate the cell response to α_1 -adrenergic stimulation.

The G protein complex is composed of the cellular receptor and the three subunits, α , β , and γ , which are involved in the cellular response to catecholamines. In the absence of a catecholamine at the receptor site, the receptor protein is bound to the β and β - γ -dimer of the G protein, and guanosine diphosphate (GDP) is bound to the α subunit. Catecholamine binding to the receptor causes a conformational change in the α subunit; GDP dissociates and guanosine triphosphate (GTP) binds to the α subunit. The α subunit (with GTP bound) then dissociates from the receptor and from the β - γ -dimer. This “activated” α subunit can now interact with adenyl cyclase or other effector enzymes. Interaction of the α_s subunit with adenyl cyclase increases the activity of the enzyme resulting in a rapid increase in the intracellular cAMP (Fig. 17-1).^{10,14,41,52,69}

FIGURE 17-1. Binding of the β -adrenergic agonist to the β receptor of a myocardial cell causes the G_s protein to activate AC to produce cAMP. The cAMP interacts with and activates PKA. Subsequent phosphorylation by PKA changes the activity of multiple other various cellular proteins, including phospholamban, calcium channels, and troponin, all of which

increase the activity of the myocardial cell. Refer to the text for more details. AC = adenylyl cyclase; cAMP = cyclic adenosine monophosphate; Ca_v-L = L-type voltage-dependent calcium channel; PKA = protein kinase A; RyR = ryanodine receptor; SR = sarcoplasmic reticulum.

cAMP acts as a secondary messenger in the cell. cAMP interacts with protein kinase A (PKA) and other cAMP-dependent protein kinases to increase their protein phosphorylating activity.⁴⁰ In the absence of cAMP, PKA is a tetramer of two regulatory and two catalytic subunits. cAMP binds to the regulatory subunits to release the active enzymatic units from the tetramer (Fig. 17-1). The activated protein kinases then transfer phosphate groups from ATP to serine (as well as to threonine and tyrosine amino acid groups) on enzymes that are involved in intracellular regulation and activities. Phosphorylation may increase or decrease the activity of specific enzymes, and specific protein kinases are highly selective in the proteins that they phosphorylate.^{75,76}

PKA phosphorylates a variety of cellular proteins involved in Ca²⁺ regulation, including the voltage-sensitive calcium channel, phospholamban, and troponin;^{27,28,74} these are all involved in the regulation and control of cellular muscle fiber contraction. Phosphorylation of the L-type calcium channel increases the entry of calcium ions into the cell during membrane depolarization.⁵⁷ Phosphorylation of phospholamban decreases its ability to inhibit the calcium ATPase pump on the sarcoplasmic reticulum (SR). This decreased inhibition of the calcium ATPase pump increases the efficiency of Ca²⁺ storage in the SR. This enhances both the cellular contractility as the Ca²⁺ is released into the cell cytosol and the relaxation of muscle fibers as the Ca²⁺ is pumped back into the SR.⁵⁷

Physiologic Effects of Adrenergic Receptor Subclasses. The existence of two types of adrenergic receptors, α and β , was first proposed in 1948 to explain both the excitatory and the inhibitory effects of catecholamines on different smooth muscle tissue.¹ The α receptor was subsequently subdivided into α_1 and α_2 when norepinephrine and other α -adrenergic agonists were found to inhibit the release of additional norepinephrine from neurons into the synapse. The α_1 -adrenergic receptors are located on postsynaptic cells outside the central nervous system, primarily on blood vessels, and mediate arteriole constriction. The “autoregulatory” α_2 -adrenergic receptors are primarily located on the presynaptic neuronal membrane and, when stimulated, decrease release of additional norepinephrine into the synapse. Additionally, some α_2 -adrenergic receptors are also found on the postsynaptic membrane in the central nervous system. Activation of these postsynaptic α_2 -receptors in the cardiovascular control center in the medulla and elsewhere in the central nervous system decreases sympathetic outflow from the brain. Thus, α_2 -adrenergic agonists generally decrease peripheral vascular resistance, decrease heart rate, and decrease blood pressure. The α_1 - and α_2 -adrenergic receptors also interact with circulating catecholamines and other sympathomimetics. The effects of sympathomimetics vary in the different organ systems due to differences in the adrenergic receptors and in the cellular responses to the receptor interactions.

The β -adrenergic receptors are subclassified into three subtypes: β_1 , β_2 , and β_3 (Table 17-1). The most prevalent β -adrenergic subtype in the heart is β_1 (80%), although β_2 (20%) and β_3 (few) receptors are also present.^{8,17,21,61} Stimulation of the β_1 -adrenergic receptors increases heart rate, contractility, conduction velocity, and automaticity. The β_2 -adrenergic receptors primarily cause relaxation of smooth muscle with resulting bronchodilation and arteriolar dilation. The β_3 receptors are located primarily on adipocytes where they play a role in lipolysis and thermogenesis.¹¹

TABLE 17-1. Types and Function of the β -Adrenergic Receptor

Type	Location	Function
β_1	Heart	Increase rate Increase inotropy Increase sinoatrial and atrioventricular node conduction
	Kidney	Increase renin
	Eye	Increase aqueous humor
	Adipose tissue	increase lipolysis
β_2	Heart	Increase rate (?) Increase inotropy
	Liver	Increase glycogenolysis Increase gluconeogenesis
	Skeletal muscle	Increase glycogenolysis
	Smooth muscle (bronchi, arterioles, gastrointestinal tract, uterus)	Relaxation
β_3	Adipose tissue	Increase lipolysis and thermogenesis
	Bladder	Increases relaxation
	Heart	Decrease inotropy (?)

The β_1 -, β_2 -, and α_2 -adrenergic receptors all interact with G_s proteins and stimulate the adenylyl cyclase enzyme. Differences in the resultant clinical effects are primarily related to the location and number of the different receptors in different tissues and to differences in the specificity of the tissue protein kinases activated by cAMP. Stimulation of the β_1 -adrenergic receptor results in increased heart rate and increased contractility. β_2 -Adrenergic receptor stimulation causes relaxation, as opposed to contraction, of smooth muscle. Because both β -adrenergic receptor subtypes interact with stimulatory G_s proteins, their clinical effects would appear to be paradoxical. However, there are two primary reasons for their different effects when G_s complexes are stimulated by β_1 - or β_2 -adrenergic agonists. First, PKA is not a single enzyme, but a group of related isoenzymes variably expressed in different tissues.^{7,30,56} The actions and the substrates of the varied protein kinase isoenzymes differs between β_1 - and β_2 -adrenergic responsive tissues. Second, whereas β_1 -adrenergic stimulation results in cAMP-mediated effects throughout the cytoplasm, β_2 -adrenergic stimulation is compartmentalized within the cell. The effect of β_2 -adrenergic stimulation of G_s type receptors is primarily localized phosphorylation of the L-type calcium channels, increasing their activity.^{13,35,87,88} Additionally, some β_2 -adrenergic receptors are also coupled to G_i -type receptors that inhibit adenylyl cyclase and prevent the diffuse cytoplasmic increases in cAMP.^{71,72,88} Also, β_2 -adrenergic receptor stimulation does not result in phosphorylation of phospholamban³⁸ or troponins.¹³

The α_2 -adrenergic receptor interacts with a G_i protein that has an inhibitory interaction with adenylyl cyclase. Binding of α_2 -adrenergic agonists to the receptor inhibits (not stimulates) adenylyl cyclase and decreases intracellular cAMP.

The α_1 -adrenergic receptors also are associated with G proteins. However, rather than being associated with G_s proteins and adenylyl cyclase, the α_1 -adrenergic receptors are associated with G_q proteins that are linked to phospholipase C.⁷⁷ Agonist binding to the receptor activates the hydrolysis of phosphatidyl inositol 4,5-bisphosphate (PIP₂) to 1,2-diacylglycerol (DAG) and inositol triphosphate (IP₃).²⁵ The IP₃ acts as an intracellular messenger, binds to receptors on the SR, and initiates the release of calcium ion.⁵ DAG activates protein kinase C, which phosphorylates slow calcium channels and other intracellular proteins, and increases the influx of calcium ion into the cell (Fig. 17-2).^{63,70,91}

FIGURE 17–2. Binding of the α -adrenergic agonist to the α_1 adrenergic receptor causes the Gq protein to activate PLC. PLC catalyzes the hydrolysis of PIP to produce DAG and IP_3 . IP_3 interacts with the RyR on the sarcoplasmic reticulum to enhance release of calcium from this cellular store. The calcium and DAG activate protein kinase C, which phosphorylates and changes the activity of various cellular proteins including phospholamban. Refer to the text for more details. $\text{Ca}_V\text{-L}$ = L-type voltage-dependent calcium channel; DAG = 1,2-diacylglycerol; IP_3 = inositol triphosphate PIP = 4,5-bisphosphate; PLC = phospholipase C; RyR = ryanodine receptor.

Many xenobiotics interact with G-protein membrane receptors and alter the intracellular cAMP or Ca^{2+} concentration. β -Adrenergic antagonist overdose results in decreased stimulation of adenylyl cyclase by G_s proteins, decreased production of cAMP, decreased activation of the cAMP-dependent kinases, and decreased Ca^{2+} release (Chap. 62). Similarly, by different mechanisms, calcium channel blocker overdose results in decreased cytoplasmic calcium concentration (Chap. 61).

Glucagon receptors, which are similar to the β -adrenergic receptors, are coupled to G_s proteins and stimulate adenylyl cyclase activity.^{2,23,38,84,89} The ability of glucagon to increase cAMP is further enhanced by its inhibitory activity on phosphodiesterase (preventing cAMP breakdown).^{18,48} Phosphodiesterase inhibitors, such as amrinone, milrinone, and enoximone, exert at least some of their inotropic activity by preventing the degradation of cAMP and enhancing calcium cycling.^{42,81,85} In a canine model of propranolol poisoning, amrinone significantly increased inotropy, stroke volume, and cardiac output.⁴²

Intracellular Calcium, Calcium Channels, and Myocyte Contractility

The contraction and relaxation cycle of the myocyte is controlled by the flux of Ca^{2+} into and out of the SR into the cytoplasm of the cell.^{15,39,66} Only a small proportion of the Ca^{2+} involved in myofibril contraction actually enters the cell through the exterior cell membrane during the action potential and membrane depolarization. The majority of the calcium is actually released from the SR of the cell invaginations of the myocyte membrane known as T-tubules place L-type calcium channels in close approximation to calcium release channels (ryanodine receptors {RyR}) on the sarcoplasmic reticulum. The local increase in Ca^{2+} concentration that follows the opening of a single L-type calcium channel triggers the opening of the associated RyR channels resulting in a large release of Ca^{2+} from the SR.¹² Myocytes contain tens of thousands of couplons, clusters of L-type calcium channels and RyR channels. The Ca^{2+} released from one couplon is not sufficient to trigger firing of neighboring couplons. Therefore, myocyte contraction requires synchronized release of Ca^{2+} from numerous couplons throughout the myocyte. The cell membrane depolarization synchronizes opening of L-type channels and subsequent Ca^{2+} release from the sarcoplasmic reticulum.^{16,57} This phenomenon of calcium-induced calcium release results in a rapid increase in the intracellular Ca^{2+} concentration and initiates a rapid myosin and actin interaction.¹⁵

At the conclusion of cellular contraction, SR-associated Ca^{2+} -adenosine triphosphatase (ATPase) pumps return the

cytosolic Ca^{2+} -ATPase into the SR. This SR associated Ca^{2+} -ATPase pump is regulated by phospholamban, a cellular protein. When phospholamban is bound to the Ca^{2+} -ATPase pump, the activity of the pump is decreased and less Ca^{2+} -ATPase is stored in the SR. Phosphorylation of phospholamban decreases its affinity for binding to the Ca^{2+} -ATPase pump. Dissociation of the phosphorylated phospholamban increases the activity of the Ca^{2+} -ATPase pump. β -Adrenergic stimulation increases protein kinase activity and leads to phosphorylation of phospholamban, dissociation of the phosphorylated phospholamban from the pump, and an increase in the total SR Ca^{2+} stores.^{19,20} The increased activity of the SR associated Ca^{2+} -ATPase pump enhances the contractility and increases the rate of relaxation of the myocytes.

Cellular contraction occurs when myosin filaments interact with the actin-tropomyosin helix. A complex of troponins T, I, and C binds to the actin helix near the myosin binding site and act as regulators of the interaction. Troponin T binds the regulatory complex to the actin helix, troponin I prevents myosin from accessing its binding site on the actin helix, and troponin C acts as a Ca^{2+} trigger to initiate contraction. When the intracellular Ca^{2+} concentration increases, 4 molecules of Ca^{2+} bind to troponin C and a conformational shift occurs in the troponin complex. Troponin I shifts away and the myosin-binding site is exposed. Myosin then binds to the exposed site and myofibril contraction occurs (Fig. 17-3).^{31,32,67,68}

FIGURE 17-3. Troponin regulation of actin and myosin interaction. On the left, TnI blocks the binding site for myosin on the tropomyosin-actin helix. On the right, calcium binding to TnC causes a conformational shift in the troponin molecules, and myosin binds to the actin helix and initiates myofibril contraction. TnC = troponin C; TnI = troponin I; TnT = troponin T.

Calcium transport through the cellular membrane ion channels is critical for normal cardiac muscle function and contractility and for maintenance of vascular smooth muscle tone. The physiologic response to calcium channel blockers and to xenobiotics that interact with the α - or β -adrenergic receptors is mediated through changes in the intracellular Ca^{2+} . Calcium channel blockers in current clinical use primarily block the L-type calcium channel, although their specificity differs for the calcium channels on the vascular smooth muscle cells versus on the myocardial cells. This results in variable effects of the different calcium channel blockers on the vascular tone and peripheral vascular resistance, and on the contractility and electrical activity of the myocardial cells. Additionally, certain calcium channel blockers interact with the neuronal calcium channels, such as the P/Q type, and are used to treat neurologic disorders such as migraine headache.

Patients poisoned by calcium channel blockers have less Ca^{2+} entry into the cell during cardiac membrane depolarization. Administration of exogenous Ca^{2+} increases the concentration gradient across the cell membrane, enhances flow through available Ca^{2+} channels, and restores the triggered response of the RyR-2 channels to release Ca^{2+} from the sarcoplasmic reticulum (Antidotes in Depth: A29). Because β -adrenergic antagonists have negative effects on Ca^{2+} handling by the SR, similar effects occur in the myocyte affected by β -adrenergic antagonists.

In the vascular smooth muscle, the cytosolic Ca^{2+} concentration maintains the basal contraction of the vascular muscle. Any decrease of Ca^{2+} influx results in relaxation and arterial vasodilation.⁵⁵ Any influx of calcium binds calmodulin, and the resulting complex stimulates myosin light-chain kinase activity.⁴⁷ The myosin light-chain kinase phosphorylates myosin. The phosphorylated myosin has increased activity for binding to actin, which causes contraction (Fig. 61-1).^{6,32}

CARDIOVASCULAR EFFECTS OF XENOBIOTICS

Xenobiotics may produce adverse effects on the cardiovascular system by acting on the myocardial cells or the autonomic nervous system to directly affect the heart rate, blood pressure, or cardiac contractility. Because metabolic abnormalities (especially acidemia, hypotension, hypoxia, and electrolyte abnormalities) can further exacerbate toxicity, or can be the sole cause of the cardiovascular abnormalities, correction of metabolic abnormalities must be a high priority in the treatment of patients with cardiovascular manifestations of poisoning. The terminal phase of any serious poisoning may include nonspecific hemodynamic abnormalities and cardiac dysrhythmias.

Heart Rate Abnormalities

Xenobiotics that directly cause dysrhythmias or cardiac conduction abnormalities usually affect the myocardial cell membrane. These abnormal rhythms, cardiac conduction abnormalities, and heart blocks are discussed in [Chap. 16](#).

Bradycardia. Sinus bradycardia is probably the most common xenobiotic-induced bradycardia. Xenobiotics ([Table 17–2](#)) produce bradycardia through different mechanisms. The xenobiotic may affect the central or peripheral nervous system or may affect rhythm generation or conduction in the heart. Most xenobiotics that cause central nervous system sedation, such as the sedative-hypnotics, opioids, and α_2 -adrenergic receptor agonist (“centrally acting”) antihypertensives, will usually decrease sympathetic outflow to the heart and produce sinus bradycardia in the range of 40 to 60 beats/min. Digoxin, certain cholinergics, and α_1 agonists may produce bradycardia and heart block through the enhancement of vagal tone. Sodium channel activators, such as aconitine, cause bradycardia due to intracellular Na^+ overload with a resultant alteration in Ca^{2+} handling. The most profound bradycardia results from overdoses of xenobiotics that have direct depressant effects on the cardiac pacemakers.⁷³ The inability to propagate an impulse within the cardiac conducting system may produce bradycardia or even asystole. Examples of xenobiotics that can produce pacemaker or conduction effects include calcium channel blockers and β -adrenergic antagonists.

Bradycardia, heart block, and asystole frequently are terminal events in patients with massive overdose of many noncardiotoxic xenobiotics. These dysrhythmias may occur as a result of direct effects on the myocardium or of indirect metabolic effects. For example, severe hyperkalemia or metabolic acidosis results in a wide complex, sinusoidal bradycardic rhythm.

Tachycardia. Sinus tachycardia is the most common rhythm disturbance that occurs in poisoned patients. Parasympatholytic drugs, such as atropine, raise the heart rate by elimination of the inhibitory vagal influence. However, more rapid rates result from direct myocardial stimulatory effects, generally mediated by β -adrenergic agonism. For example, catecholamine excess (eg, cocaine, psychomotor agitation, methylxanthines, sedative-hypnotic withdrawal) may cause sinus tachycardia with rates faster than 150 beats/min. Tachycardia may also be an indirect effect in response to hypotension, hypoxia, acidemia, fever electrolyte abnormalities, and other metabolic derangements that may be present in poisoned patients ([Table 17-3](#)).

Decreased Cardiac Contractility and Congestive Heart Failure

Xenobiotics can reduce cardiac contractility with a resulting decrease in cardiac ejection fraction and cardiac output, a decrease in blood pressure, and development of congestive heart failure (CHF). Cardiogenic pulmonary edema generally occurs as a result of the direct effects of the xenobiotic on the contractility, or inotropy, of the heart, or through increases in the preload or afterload. Acute cardiogenic pulmonary edema, resulting from impaired left heart filling (which may be due to decreased cardiac output), occurs in patients poisoned by a nondihydropyridine calcium channel blocker or β -adrenergic receptor antagonist. Other xenobiotics that can exert direct depressant effects on cardiac contractility include antihistamines, phenothiazines, antidysrhythmics, and local anesthetics. Many of these xenobiotics reduce contractility through sodium channel blockade, which, by slowing intraventricular conduction, reduces the ability of the heart to contract efficiently. Pulmonary edema may also result from the fluid overload accompanying ingestion of large quantities of sodium-containing xenobiotics (eg, sodium penicillin), the renal effects of medications such as nonsteroidal antiinflammatory drugs, or as a late consequence of xenobiotics that cause kidney failure ([Chap. 28](#)).

Xenobiotics can cause cardiomyopathy through chronic toxic effects directly on the myocardium or indirectly through effects on blood pressure or cardiac vasculature ([Table 17–4](#)). In most cases, the exact mechanism of the toxicity is not known. However, free radical generation, nitric oxide formation, acetaldehyde production, myocardial ischemia, mechanical overload, nutritional deficiency, and persistent tachycardia are each implicated in the cellular toxicity of the various xenobiotics and development of cardiomyopathy.

Blood Pressure Abnormalities

Blood pressure is dependent upon cardiac and vascular function. The blood pressure is directly related to the heart rate (HR), the stroke volume (SV), and the systemic vascular resistance (SVR): $\text{Blood pressure} = \text{HR} \times \text{SV} \times \text{SVR}$. The systolic component of the blood pressure measurement is a reflection of the inotropic state of the myocardium, whereas the diastolic component reflects the vascular tone. It is important to consider both components of the blood pressure. Blood pressure may be expressed also as the mean arterial pressure (MAP) during a single cardiac cycle. Since at normal heart rates the duration of diastole is approximately twice that of systole, the MAP is calculated as $(\{2 \times \text{diastolic}\} + \{\text{systolic}\})/3$. Xenobiotics may affect either component, and compensatory mechanisms within the cardiovascular system may produce recognizable patterns of blood pressure alterations.

Many xenobiotics affect blood pressure by modulation of normal neurotransmission at the postganglionic sympathetic neurons. Through these interactions they may cause, for example, vasoconstriction with an α -adrenergic agonist or increased inotropy with a β_1 -adrenergic agonist. Because of the functional similarity of most sympathomimetics, physical examination alone seldom identifies the specific causative xenobiotic in any tachycardic patient. However, often a clinical constellation of signs and symptoms can be identified that is associated with this general class. For example, patients who ingest sympathomimetic amines such as cocaine or amphetamines typically have central nervous system stimulation, hypertension, and tachycardia ([Chap. 3](#)).

Hypertension Caused by Xenobiotics. Hypertension may be the result of an increase in either inotropy or vascular resistance or both. For example, stimulation of the α_1 -adrenergic receptor causes hypertension through vasoconstriction, and stimulation of the β_1 -adrenergic receptor causes hypertension through enhanced myocardial contractility ([Table 17–5](#)).

TABLE 17–5. Xenobiotics that Commonly Cause Hypertension

<i>Hypertensive Effects Mediated by α-Adrenergic Receptor Interaction</i>	<i>Hypertensive Effects Not Mediated by α-Adrenergic Receptor Interaction</i>
Direct α -adrenergic receptor agonists	β -Adrenergic receptor agonists ^b
Clonidine ^a	Nonselective

Dopamine	
Ephedrine	
Metaraminol	
Naphazoline	
Oxymetazoline	
Phenylpropanolamine	
Pseudoephedrine	

^aThese may cause transient hypertension followed by hypotension. ^bThese may cause hypotension.

The hemodynamic results of a xenobiotic overdose depend on the specific xenobiotic ingested and the relative action on the various types of receptors. This suggests that, among β -adrenergic agonists, only those with a predominant β_1 -adrenergic effect cause hypertension. Nonselective β -adrenergic agonists (those that agonize at both β_1 and β_2) produce β_1 -mediated systolic hypertension (through inotropic effects) with β_2 -mediated vascular vasodilation and diastolic hypotension. This may result in a widened pulse pressure, which is the numerical difference between the systolic and diastolic pressures. Exposure to selective β_2 -adrenergic agonists (eg, albuterol) may also result in tachycardia and enhanced inotropy with a widened pulse pressure in a manner analogous to nonselective β agonists. The resulting blood pressure depends on the relative physiologic balance between inotropy and vasodilation.

Xenobiotics that interact only with the α_1 -adrenergic receptor (such as phenylephrine) cause vasoconstriction and hypertension. Baroreceptors detect the increased blood pressure and signal the parasympathetic nervous system neurons of the vagus nerve to fire and slow the heart rate. In the absence of β -adrenergic stimulation, a “reflex” bradycardia results. Norepinephrine is an α_1 -adrenergic agonist with additional β -adrenergic activity. Profound hypertension is the primary hemodynamic toxic effect due to the activity of norepinephrine as both a positive inotrope (β_1) and a vasoconstrictor (α_1). Reflex bradycardia does not occur as a result of stimulation of the cardiac β_1 -adrenergic receptors.

Hypotension Caused by Xenobiotics. Typically, hypotension in adults is arbitrarily defined as a systolic blood pressure of less than 90 mm Hg or a MAP of less than 70 mm Hg. However, this is not an adequate clinical parameter. Young children and adults with a small body habitus may have a normal systolic pressure less than 90 mm Hg ([Chap. 3](#)). Patients with hypothermia have decreased metabolic demands, and a lower blood pressure may be considered “normal” for these patients. Most importantly, patients with long-standing hypertension may have inadequate tissue perfusion even with a MAP of more than 70 mm Hg. The cerebral arterioles normally constrict or dilate to maintain a relatively constant cerebrovascular blood flow despite changes in the peripheral blood pressure. Chronically hypertensive patients lose this autoregulatory response as a consequence of atherosclerotic disease, arteriolar hypertrophy, or arteriolar smooth muscle constriction. These narrowed arterioles may require a higher peripheral blood pressure to properly perfuse the brain.

Clinically, hypotension is defined as blood pressure that is inadequate to perfuse tissues. The clinical assessment of tissue perfusion is based on the vital signs, skin color, capillary refill, mental status, urine output and concentration, and acid–base balance (eg, serum lactate concentration). However, if a xenobiotic directly affects one or more of these

parameters, the clinical assessment of volume and hemodynamic status may be difficult. Measurement of central venous pressure is beneficial in the early treatment of the sepsis syndrome, and most likely would be beneficial in the treatment of other causes of hypotension, including those occurring in poisoned patients. Ultrasound of the inferior vena cava (IVC) has been shown to be useful for assessing volume status and estimating central venous pressure (CVP).^{34,51,83,90} Invasive measurement of cardiac filling pressure, cardiac output, systemic vascular resistance, and arterial pressures may be necessary in critically ill patients with severe poisoning.^{64,65}

Poor tissue perfusion may result from hypovolemia, decreased peripheral vascular resistance, myocardial depression, or a dysrhythmia that reduces cardiac output. A single xenobiotic may exert several effects on the hemodynamic system, such as diltiazem, a calcium channel blocker that causes negative inotropy and vasodilation. Appropriate treatment of the hypotension requires an understanding of the pathophysiologic consequences of the xenobiotic and the resultant hemodynamic derangement (Table 17–6).

Hypotension in a poisoned patient may also be due to intravascular volume depletion. Intravascular volume may decrease due to gastrointestinal, urinary, or insensible losses; or fluid may redistribute from the intravascular space into the intracellular, interstitial, pleural, or peritoneal spaces. Xenobiotics can cause significant intravascular volume depletion through all of these mechanisms.

Hypotension may also be caused by xenobiotics that affect venous tone. These xenobiotics increase venous capacitance, decrease the central venous pressure, and result in relative hypovolemia. The effects may be mediated via central effects on the sympathetic nervous system or direct effects on the peripheral vasculature. Sedative hypnotics and central α_2 -adrenergic agonists (eg, clonidine) decrease the central sympathetic outflow and may result in hypotension. Other xenobiotics directly block peripheral α_1 -adrenergic receptors or stimulate β_2 -adrenergic receptors on the blood vessels to produce vascular smooth muscle relaxation, venodilation, and hypotension. A large number of xenobiotics are reported to cause hypotension; however, the hypotension often is not a direct action of the xenobiotic. Rather, the cause of hypotension is coexisting hypoxia, acidemia, anaphylaxis, volume depletion, or dysrhythmias.

Identification of the specific xenobiotic causing hypotension requires the integration of a detailed history, complete physical examination, and laboratory studies. Often the identification of the specific xenobiotic responsible for hypotension is based on other physical findings associated with the xenobiotic or recognition of a specific toxic syndrome.

ASSESSMENT OF VOLUME STATUS IN THE POISONED PATIENT

Assessment of volume status may be particularly difficult in the poisoned patient because of functional alterations in the patient’s autonomic nervous system and the pharmacologic effects of the xenobiotic. For example, the usual signs of salt and water depletion, such as dry mucous membranes, dry skin, low blood pressure, tachycardia, narrowed pulse pressure, clouded sensorium, and decreased urine output, can be mimicked by a number of xenobiotics, including tricyclic antidepressants. Additionally, hypovolemic patients may present with diaphoresis, flushed skin, hypertension, bradycardia, or increased urine output following exposure to a cholinergic xenobiotic such as an organic phosphorus compound. In most cases, clinical assessment of CVPs and neck vein distension or the hemodynamic response to a fluid bolus can assist in the determination of the patient’s volume status. A central venous or pulmonary artery pressure catheter may be required in some critically ill patients.

Additional information about the patient’s volume status can potentially be obtained with ultrasound measurements of the IVC. Ultrasound can noninvasively measure the IVC size and variation with respiration correlates with volume status.^{34,90} Studies demonstrate that a decrease of more than 50% in the IVC diameter from expiration to inspiration correlates with a CVP of less than 8 mm Hg.⁵¹ However, other studies find that this index varies significantly by the chosen location for the ultrasound measurements.⁸³ Furthermore, there is a poor correlation between the ultrasound CVP determination and actual measured CVP.⁵⁴ Other ultrasound venous measurements have also been tested including the internal jugular vein³³ and compression ultrasound of a forearm vein, IVC collapsibility, and internal jugular vein collapsibility with only moderate correlation with the actual CVP.⁸² While ultrasound may not be absolutely predictive of the volume status, the information can be useful as an adjunct to clinical assessment of hydration status and end organ perfusion.

Additional information about the adequacy of the patient’s volume status may be obtained by orthostatic vital sign testing (Table 17–7).²¹ Normally, the cardiovascular system responds to sitting or standing with vasoconstriction and a slight increase in heart rate. Even with a 30% or greater volume loss, the supine blood pressure may remain normal in young, previously healthy patients. However, patients with hypovolemia are unable to maintain adequate intravascular pressure when upright and have either an exaggerated reflex increase in heart rate or a drop in blood pressure (ie, orthostasis).

TABLE 17–7. Orthostatic Vital Signs (“Tilt” Testing)

1. After the patient is supine for 2 min, determine the blood pressure and pulse rate.
2. Stand the patient for at least 1 min and determine the blood pressure and pulse rate again, and observe for any orthostatic symptoms such as dizziness or lightheadedness. If it is impossible for the patient to stand, have the patient sit up with feet dangling for at least 2 min before determining vital signs.

The test is positive if any one of the following is true:

Systolic blood pressure decreases > 20 mm Hg

Diastolic blood pressure decreases > 10 mm Hg

Pulse increases > 10 beats/min

Development of clinical symptoms of hypovolemia (dizziness, syncope, lightheadedness)

Significance of a positive test: corresponds roughly to 10 to 15 mL/kg volume loss

A variety of xenobiotics can produce orthostatic blood pressure changes (Table 17–8).^{24,44} Volume depletion is the most common cause of xenobiotic-induced orthostatic vital sign changes. However, xenobiotics may produce orthostatic vital sign changes even with a normal volume status. For instance, α_1 -adrenergic antagonists or direct-acting vasodilators may prevent an adequate vasoconstrictor response or β -adrenergic antagonists may block the normal slight heart rate increase, and result in positive orthostatic vital sign testing. In these cases, cardiac output and blood pressure decrease when the patient is upright.

Prazosin

While various assessments can be useful for predicting the volume status, the most accurate immediate assessment is probably the demonstration of increased cardiac output after a fluid challenge. The passive leg-raising test may be used as a bedside test to evaluate the adequacy of fluid resuscitation. The test is performed by having the patient sit upright in a semi-recumbent position at about 45 degrees. The head is then lowered to the recumbent position and the legs are raised to about 45 degrees. This transiently increases the circulatory volume by around 130 to 300 mL, and it may result in changes in the arterial pressure and heart rate.^{29,50} Several studies have shown that this simple maneuver is a good predictor of hemodynamic response to a fluid bolus especially in intensive care patients.^{36,37,43,45,46,49,80}

Definitive care of the poisoned patient with hemodynamic compromise or a dysrhythmia begins with recognition that a xenobiotic may be present. Infectious, cardiovascular disease, and other metabolic disorders must always be considered; however, the toxic effects of xenobiotics must be included in the differential diagnosis. A variety of clinical clues, when present, should heighten the clinician's suspicion that a xenobiotic effect may be responsible for the hemodynamic or dysrhythmic problem (Table 17–9).

TABLE 17–9. Clues That an Unanticipated Xenobiotic Might Be Causing Hemodynamic Compromise or Dysrhythmia

History

Concomitant seizure

Gastrointestinal disturbances (colicky pain, nausea, vomiting, diarrhea)

Prior ingestion of medications (consider possibility that the container is mislabeled or misidentified)

Depression (even if patient denies ingestion)

Suspected myocardial ischemia in patient < 35 years old

Past Medical History

Treatment with any cardiac medications (especially antidysrhythmics or digoxin)

History of psychiatric illness, asthma, or hypertension

History of drug use or abuse

Physical examination and vital signs

Heart rate

Sinus tachycardia with rate >130 beats/min

Sinus tachycardia without apparent identified cause

Sinus bradycardia

Respiratory rate

Any unexplained depression or elevation in rate

Temperature

Hyperthermia especially if $> 106^{\circ}\text{F}$ ($> 41.1^{\circ}\text{C}$)

Hypothermia if $< 86^{\circ}\text{F}$ ($< 30^{\circ}\text{C}$)

Dissociation between typically paired changes, for example:

Hypotension and bradycardia (tachycardia expected)

Fever and dry skin (diaphoresis expected)

Hypertension and tachycardia (reflex bradycardia anticipated)

Depressed mental status and tachypnea (decreased respirations common)

Relatively rapid changes in vital signs

Initial hypertension becomes hypotension

Increasing sinus tachycardia or hypertension

General

Alteration in consciousness, such as depressed mental status, confusion, or agitation

Findings usually not associated with cardiovascular diseases

Ataxia, bullae, dry mucous membranes, lacrimation, miosis or mydriasis, nystagmus, unusual odor, flushed skin, salivation, tinnitus, tremor, visual disturbances

Findings consistent with a toxic syndrome

Especially findings consistent with anticholinergics, sympathomimetics, or sedative hypnotics

Laboratory Tests

Any unexpected or unexplained laboratory result, especially:

Metabolic acidosis

Respiratory alkalosis

Hypokalemia or hyperkalemia

SUMMARY

- Xenobiotics can interact with the heart or blood vessels to produce hypotension or hypertension, congestive heart failure, dysrhythmias (including bradycardias and tachycardias), or cardiac conduction delays.
- These toxic effects often occur through interactions with specific receptors or with the ion channels in the cell membrane.
- Disruption of the normal cellular regulation of metabolic processes or of the cellular ionic status leads to the cardiovascular and hemodynamic compromise.
- The occurrence of these abnormalities, individually or in combination, might suggest a particular xenobiotic or class of xenobiotics as the etiologic (toxic syndrome) and might dictate initial treatment. However, often significant abnormalities in vital signs must be corrected before the xenobiotic is identified.
- By understanding both the pharmacology of the xenobiotic and the physiology of the heart and vasculature, appropriately tailored treatment can be delivered.

18 DERMATOLOGIC PRINCIPLES

Jesse M. Lewin, Neal A. Lewin, and Lewis S. Nelson

INTRODUCTION

Dermatology is a specialty in which visual inspection may allow for rapid diagnosis. Some authors suggest a brief examination before a lengthy history because some of the classic skin diseases with obvious morphologies allow a “doorway diagnosis” to be established. The tools the physician needs are readily available and include a magnifying glass, glass slide (for diascopy), flashlight, alcohol pad to remove scale or makeup, scalpel, and at times a Wood’s lamp. Universal precautions should always be used.

The ability to describe lesions accurately is an important skill, as is the ability to recognize specific patterns. These abilities aid clinicians in their approach to the patient with a cutaneous eruption both in developing a differential diagnosis and while communicating with other physicians. The classic dermatologic lesions are defined in [Table 18–1](#).

TABLE 18–1. Dermatologic Diagnostic Descriptions of Lesions of the Skin

<i>Primary Cutaneous Lesions</i>	<i>Secondary Cutaneous Lesions</i>
Comedone: open and closed dilated pores (blackheads and whiteheads, respectively)	Erosion: a loss of the epidermis up to the full thickness of the epidermis but not through the basement membrane
Macule: a circumscribed flat variation of color that may be brown, blue, yellow, red, or hyper- or hypopigmented, <1 cm	Ulcer: a loss of full-thickness epidermis and papillary dermis, reticular dermis, or subcutis
Patch: a circumscribed flat variation of color that may be brown, blue, yellow, red, or hyper- or hypopigmented, >1 cm	Lichenification: thickening of the epidermis and accentuation of natural skin lines
Papule: a circumscribed elevation of <1 cm in diameter	Atrophy: thinning of the epidermis
Plaque: a circumscribed elevation of >1 cm in diameter	Scale: flaking caused by accumulation of stratum corneum (hyperkeratosis) or delayed desquamation
Nodule: a circumscribed elevation often >2 cm in diameter, involves the dermis and at times subcutis	Scar: a thickened, often discolored surface
Pustule: a circumscribed collection of purulent fluid that varies in size	
Tumor: an elevation of >0.5 cm in diameter	
Vesicle: a circumscribed collection of clear fluid <1 cm in diameter	
Bulla: a circumscribed collection of clear fluid >1 cm in diameter	
Wheal: a firm edematous plaque resulting from infiltration of the dermis with fluid	

The skin shields the internal organs from harmful xenobiotics in the environment and maintains internal organ integrity. The adult skin covers an average surface area of 2 m². Despite its outwardly simple structure and function, the skin is extraordinarily complex. The skin can be affected by xenobiotic exposures that occur through many routes. Dermal exposures themselves are important because they account for approximately 1% of the fatalities reported to the American Association of Poison Control Centers (AAPCC) ([Chap. 136](#)). The clinician must obtain essential information as to the dose, timing, route, and location of exposure. Knowledge of the physical and chemical properties of the xenobiotic can be

used to make relevant predictions of adverse cutaneous reaction and whether the response will be local or systemic. The location of xenobiotic injury determines the histologic morphology, the severity of the reaction pattern, and the overall clinical findings. It should be noted, however, that different xenobiotics may produce clinically similar skin changes and conversely that an individual xenobiotic may produce diverse cutaneous lesions.

SKIN ANATOMY AND PHYSIOLOGY

The skin has three main components that interconnect anatomically and interact functionally: the epidermis, the dermis, and the subcutis or hypodermis (Fig. 18–1). Some experts further categorize the components of the skin into three reactive units: The superficial reactive unit, which is composed of the epidermis, the dermal–epidermal junction (DEJ), and the superficial or papillary dermis with its vascular system; the dermal reactive unit, which is composed of the reticular layer of the dermis and the dermal microvascular plexus; and the subcutaneous reactive unit, which consists of fat lobules and septae.³⁶ The primary physiologic roles of the epidermis, the outermost layer of the skin, are to serve as a barrier, maintain fluid balance, and prevent infection. The degree of barrier function of the epidermis varies with the thickness of the epidermis, which ranges from 1.5 mm on the palms and soles to 0.1 mm on the eyelids. The epidermis is composed of four layers: the horny layer (stratum corneum); granular layer (stratum granulosum); spinous layer (stratum spinosum); and basal layer (stratum germinativum), which overlies the basement membrane zone (BMZ) (Fig. 18–1). The keratinocyte, or squamous cell, which is an ectodermal derivative, comprises the majority of cells in the epidermis.

FIGURE 18–1. Skin histology and pathology. Intraepidermal cleavage sites in various xenobiotic-induced blistering diseases. Whereas in pemphigus foliaceus, the cleavage is below or within the granular layer; in pemphigus vulgaris, it is suprabasilar. This accounts for the differing types of blisters found in the two diseases. HF = hair follicle.

The stratum corneum, a semipermeable surface composed of differentiated keratinocytes, is predominantly responsible

for the physical barrier function of the skin. Disruption or abnormal formation of the stratum corneum leads to inadequate function of this barrier, whether by disorders of proliferation or desquamation. For example, accelerated cornification leads to retained nuclei in the stratum corneum (parakeratosis), causing gaps in the stratum corneum as in psoriasis, which impedes barrier function.³⁶ Alternately, in some forms of ichthyosis, there may be decreased desquamation, leading to epidermal retention, which influences the barrier function of the stratum corneum.⁴ Barrier function is also partly maintained by the upper spinous and granular layers. In this layer, there are Odland bodies, also known as membrane-coating granules, lamellar granules, and keratinosomes. The contents of these organelles provide a barrier to water loss while mediating stratum corneum cell cohesion.¹⁸ The stratum corneum is covered by a surface film composed of sebum emulsified with sweat and breakdown products of keratinocytes.³² This surface film functions as an external barrier as protection from the entry of bacteria, viruses, and fungi. The role of the surface film, however, is limited with regard to percutaneous absorption. The major barrier molecules to percutaneous absorption in the skin are lipids called ceramides.³² Diseases characterized by dry skin, such as atopic dermatitis and psoriasis, are in part caused by decreased concentrations of ceramide in the stratum corneum, which allows increased xenobiotic penetration because of barrier degradation.³² Similarly, hydrocarbon solvents, such as gasoline or methanol, and detergents commonly produce a “defatting dermatitis” by keratolysis or the dissolution of these surface lipids.

The cells of the basal layer control the renewal of the epidermis. The basal layer contains stem cells and transient amplifying cells, which are the proliferative cells resulting in new epidermal formation that occurs approximately every 28 days.³⁶ As the basal cells migrate toward the skin surface, they flatten, lose their nuclei, develop keratohyalin granules, and eventually develop into keratinocytes of the stratum corneum. The basal layer of the epidermis is just above the BMZ and is populated by melanocytes and Langerhans cells in addition to basal keratinocytes. Melanocytes contain melanin, which is the major chromophore in the skin that is responsible for absorbing ultraviolet (UV) and other light energies. Melanocytes are primarily responsible for producing skin pigmentation. Langerhans cells are bone marrow–derived dendritic cells with a primary role in immunosurveillance. These cells function in the recognition, uptake, processing, and presentation of antigens to previously sensitized T lymphocytes. In addition, Langerhans cells may carry antigens via dermal lymphatics to regional lymph nodes.

The BMZ consists of three layers—the lamina lucida, the lamina densa, and the sublamina densa—and separates the epidermis from the dermis (Fig. 18–1). It provides a site of attachment for basal keratinocytes and permits epidermal–dermal interaction. The BMZ is also of clinical significance because it is the target of genetic defects and autoimmune attack leading to a variety of inherited and acquired cutaneous diseases.

The DEJ provides resistance against trauma, gives support to the overlying structures, organizes the cytoskeleton in the basal cells, and serves as a semipermeable barrier. The dermis below the DEJ contains the adnexal structures, blood vessels, and nerves. It is arranged into two major regions, the upper papillary dermis and the deeper reticular dermis. The dermis provides structural integrity and contains many important appendageal structures. The structural support is provided by both collagen and elastin fibers embedded in glycosaminoglycans, such as chondroitin A and hyaluronic acid. Whereas collagen accounts for 70% of the dry weight of the skin, elastic fibers comprise only 1% to 2% of the skin’s dry weight. Several important cells, including fibroblasts, macrophages, and mast cells, are residents of the dermis, each with its own unique function. Traversing the dermis are venules, capillaries, arterioles, nerves, and glandular structures.

The arteriovenous framework of the skin is derived from a deep plexus of perforating vessels within the skeletal muscle and subcutaneous fat. From this deep plexus, smaller arterioles transverse upward to the junction of the reticular and papillary dermis, where they form the superficial plexus. Capillary venules form superficial vascular loops that ascend into and descend from the dermal papillae (Fig. 18–1). The communicating blood vessels provide channels through which xenobiotics exposed on the skin surface can be transported internally. This circulatory network provides nutrition for the tissue and is involved in temperature and blood pressure regulation, wound repair, and numerous immunologic events.¹² Parallel to the vasculature are cutaneous nerves, which serve the dual function of receiving sensory input and carrying sympathetically mediated autonomic stimuli that induce piloerection and sweating.²¹

The apocrine glands consist of secretory coils and intradermal ducts ending in the follicular canal. The secretory coil is located in the subcutis and consists of a large lumen surrounded by columnar to cuboidal cells with eosinophilic cytoplasm.²¹ Apocrine glands, which are concentrated in select areas of the body such as the axilla, produce secretions that are rendered odoriferous by cutaneous bacterial flora.

The eccrine glands, in contrast, produce an isotonic to hypotonic secretion that is modified by the ducts and emerges on the skin surface as sweat. The eccrine unit consists of a secretory gland as well as intradermal and intraepidermal ducts. The coiled secretory gland is located in the area of the deep dermis and subcutis. Xenobiotics can be concentrated in the sweat and increase the intensity of the local skin reactions. Certain antineoplastics, such as cytarabine and bleomycin, directly damage the eccrine sweat glands, resulting in anhidrosis.

Sebaceous glands also reside in the dermis. They produce an oily, lipid-rich secretion that functions as an emollient for the hair and skin, and can be a reservoir of noxious environmental xenobiotics. Pilosebaceous follicles, which are present all over the body, consist of a hair shaft, hair follicle, sebaceous gland, sensory end organ, and erector pili. Certain

halogenated aromatic chemicals, such as polychlorinated biphenyls (PCBs), dioxin, and 2,4-dichlorophenoxyacetic acid, are excreted in the sebum and cause hyperkeratosis of the follicular canal. This produces a syndrome, chloracne, that appears clinically similar to severe acne vulgaris but predominates in the malar, retroauricular, and mandibular regions of the head and neck and typically develops after several weeks of exposure (Fig. 18–2). Similar syndromes result from exposure to brominated and iodinated compounds and are known as bromoderma and ioderma, respectively.⁶⁶

FIGURE 18–2. Chloracne caused by dioxin poisoning. Comedones and papulopustular lesions, nodules, and cysts have led to a gross deformity of the nose. (Used with permission of Dr. Alexandra Geusau.)

The subcutis serves to insulate, cushion, and allow for mobility of the overlying skin structures. Adipocytes represent the majority of cells found in this layer. Leptin, an adipose-derived hormone responsible for long-term feedback of appetite and satiety signaling, is synthesized and regulates fat mass (adiposity) in this layer.

The hair follicle is divided into three portions, the hair bulb, infundibulum, and isthmus.⁵⁵ The deepest portion of the hair follicle contains the bulb with matrix cells. The matrix cells are highly mitotically active and often are the target of cytotoxic xenobiotics. The rate of growth and the type of hair are unique for different body sites. Hair growth proceeds through three distinct phases: the active prolonged growth phase (anagen phase) during which matrix cell mitotic activity is high; a short involutional phase (catagen phase); and a resting phase (telogen phase). The length of anagen phase determines the final length of the hair and varies depending on site of the body. For example, hair on the scalp has the longest anagen phase ranging from 2 to 8 years with hair growth at a rate of 0.37 to 0.44 mm/d.³⁶ Understanding the phases of hair growth is important because hair growth can be used to identify clues regarding the timing and mechanism of action of a xenobiotic.

The nail plate, which is often considered analogous to the hair, is also a continuously growing structure. Fingernails grow at average of 0.1 mm/d, and toenails grow at about one-third that rate. The mitotically active cells of the nail matrix that produce the nail plate are subject to both traumatic and xenobiotic injury, which in turn affect the appearance and growth of the nail plate. Because nail growth is consistent, location of an abnormality in the plate, such as Mees lines (transverse white lines), can predict the timing of exposure.

TOPICAL TOXICITY

Transdermal Xenobiotic Absorption

Although there is no active uptake mechanism for xenobiotics by the skin, many undergo percutaneous absorption by passive diffusion. Lipid solubility, concentration gradient, molecular weight, and certain specific skin characteristics are important determinants of dermal absorption.^{22,23,48,52} Absorption is determined to a great extent by the lipid solubility of the specific xenobiotic.^{15,37} The pharmacokinetic profile of transdermally administered xenobiotics is markedly different than by the enteral or other parenteral routes.¹⁷ As with any route of administration, adverse effects and toxicity caused by excessive absorption after patch application may occur after therapeutic use and misuse. For example, adverse effects and toxicity are reported with nicotine, fentanyl, nonsteroidal antiinflammatory drugs (NSAIDs), and lidocaine transdermal delivery devices. Other xenobiotics, topically applied without a specific delivery device, including podophyllin, camphor, phenol, organic phosphorus compounds, ethanol, organochlorines, nitrates, and hexachlorophene, may be associated with systemic toxicity and mortality (Special Considerations: SC1).

Direct Dermal Toxicity

Exposure to any one of a myriad of industrial and environmental xenobiotics can result in dermal “burns.” Although the majority of these xenobiotics injure the skin through chemical reactivity rather than thermal damage, the clinical appearances of the two are often identical. Injurious xenobiotics may act as oxidizing or reducing agents, corrosives, protoplasmic poisons, desiccants, or vesicants. Often an injury may initially appear to be mild or superficial with minimal erythema, blanching, or discoloration of the skin. Over the subsequent 24 to 36 hours, there may be progression to extensive necrosis of the skin and subcutaneous tissue.

Both inorganic and organic acids are capable of penetrating and damaging the epidermis via protein denaturation and cytotoxicity; however, organic acids tend to be less irritating. The damaged tissue coagulates and forms a thick eschar that limits the spread of the xenobiotic. The histopathologic finding after acid injury is termed coagulative necrosis.¹⁰ Inorganic acids that are frequently used in industry include hydrochloric and sulfuric acids, but the weakly acidic hydrofluoric (HF) acid that is used for the etching of glass, metal, and stone leads to the severe injury. HF acid, because of its limited dissociation constant, is able to penetrate intact skin with subsequent penetration into deeper tissues. The fluoride ion is an extremely cytotoxic agent, causing severe tissue damage, including bone destruction, by interfering with a variety of cellular enzyme systems. Severe pain is caused by the capacity of fluoride ions to bind tissue calcium, thus affecting nerve conduction.⁵⁸ In the dermis, the proton (H^+) and fluoride ions (F^-) may ionize and cause both acid-induced tissue necrosis and fluoride-induced toxicity (Chap. 107).⁵

Alkali exposures characteristically produce a liquefactive necrosis, which allows continued penetration of the corrosive xenobiotic. Consequently, cutaneous and subcutaneous injury after alkali exposure is typically more severe than after an acid exposure, with the exception of HF acid. With alkali burns, there are generally no vesicles but rather necrotic skin caused by the disruption of barrier lipids and denaturation of proteins with subsequent fatty acid saponification. Common strong alkalis include sodium, ammonium, and potassium hydroxide; sodium and potassium carbonate; and calcium oxide. These are used primarily in the manufacture of bleaches, dyes, vitamins, pulp, paper, plastics, drain openers, and soaps and detergents. Alkali burns from wet cement result from the liberation of calcium hydroxide, which has an initial pH of 10 to 12 that rises to 12 to 14 as the cement sets.³⁵

Thermal damage can also be the result of a xenobiotic exposure. For example, the exothermic reaction generated by the wetting of elemental phosphorus or sodium may result in a thermal burn. In these circumstances, the products of reactivity, phosphoric acid, and sodium hydroxide, respectively, may produce secondary chemical injury. Alternatively, skin exposure to a rapidly expanding gas, such as nitrous oxide from a whipped cream cartridge or compressed liquefied nitrogen, or to frozen substances, such as dry ice (CO_2), can produce a freezing injury, or frostbite.

Hydrocarbon-based solvents are typically liquids that are capable of dissolving non-water-soluble solutes.¹⁰ Although the most prominent effect is a dermatitis caused by loss of ceramides from the stratum corneum of the epidermis, prolonged exposure can result in deeper dermal irritation and pressure and hydrocarbon skin exposure.

PRINCIPLES OF DERMAL DECONTAMINATION

On contact with xenobiotics, the skin should be thoroughly cleansed to prevent direct effects and systemic absorption. In general, water in copious amounts is the decontaminant of choice for skin irrigation. Soap should be used when adherent xenobiotics are involved. After exposures to airborne xenobiotics, the mouth, nasal cavities, eyes, and ear canals should be irrigated with appropriate solutions such as water or a 0.9% NaCl solution. For nonambulatory patients, the decontamination process may be conducted using special collection stretchers if available.⁹

There are a few situations in which water should not be used for skin decontamination. These situations include contamination with the reactive metallic forms of the alkali metals, sodium, potassium, lithium, cesium, and rubidium, which react with water to form strong bases. The dusts of pure magnesium, sulfur, strontium, titanium, uranium, yttrium, zinc, and zirconium will ignite or explode on contact with water. After exposure to these metals, any residual metal should be removed mechanically with forceps, gauze, or towels and stored in mineral oil. Phenol, a colorless xenobiotic used in the manufacturing of plastics, paints, rubber, adhesives, and soap, has a tendency to thicken and become difficult to remove after exposure to water. Suggestions for phenol decontamination include alternating washing with water and polyethylene glycol (PEG 400) or 70% isopropanol for 1 minute each for a total of 15 minutes.³⁸ Calcium oxide (quicklime) thickens and forms $Ca(OH)_2$ after exposure to water, which releases heat and causes cutaneous ulcerations, suggesting that mechanical removal as above is advised.

DERMATOLOGIC SIGNS OF SYSTEMIC DISEASES

Cyanosis

Normal cutaneous and mucosal pigmentation is caused by several factors, one of which is the visualization of the capillary

beds through the translucent epidermis and dermis. Cyanosis manifests as a blue or violaceous appearance of the skin, mucous membranes, and nailbeds. It occurs when excessive concentrations of reduced hemoglobin (>5 g/dL) are present, as in hypoxia or polycythemia, or when oxidation of the iron moiety of heme to the ferric state (Fe^{3+}) forms methemoglobin, which is deeply pigmented (Chap. 127). The presence of the more deeply colored hemoglobin moiety within the dermal plexus results in cyanosis that is most pronounced on areas of thin skin such as the mucous membranes or underneath fingernails. Also, in the differential diagnosis for a patient with discoloration of the skin is pseudochromhidrosis, also termed extrinsic apocrine chromhidrosis. This results from staining of the sweat by chromogenic bacteria, including *Corynebacterium*, *Malassezia furfur*, and *Bacillus* species; the latter two species have been known to cause blue discoloration of the skin. Several cases of blue pseudochromhidrosis caused by topiramate use are reported in the literature; the diagnosis can be made by the ability of the clinician to wipe off the discoloration with a damp cotton swab.¹¹

Xanthoderma

Xanthoderma is a yellow to yellow-orange macular discoloration of the skin.²⁵ Xanthoderma can be caused by xenobiotics such as carotenoids, which deposit in the stratum corneum, and cause carotenoderma. Carotenoids are lipid soluble and consist of α -carotene, β -carotene, β -cryptoxanthin, lycopene, lutein, and zeaxanthin and serve as precursors of vitamin A (retinol). The carotenoids are excreted via sweat, sebum, urine, and gastrointestinal (GI) secretions. Jaundice is typically a sign of hepatocellular failure or hemolysis and is caused by hyperbilirubinemia, either conjugated or unconjugated, a condition in which the yellow bilirubin deposits in the subcutaneous fat, leading to a common cause of xanthoderma. Jaundice caused by hyperbilirubinemia from liver failure may be accompanied by other cutaneous stigmata, including spider angiomas, telangiectasias, palmar erythema, and dilated superficial abdominal veins (caput medusa). True hyperbilirubinemia is differentiated from hypercarotenemia by the presence of scleral icterus in patients with the former, which is absent in patients with the latter. In addition, the cutaneous discoloration seen in hypercarotenemia can be removed by wiping the skin with an alcohol swab. Lycopopenia, an entity similar to carotenemia, is caused by the excessive consumption of tomatoes. Additionally, topical exposure to dinitrophenol or picric acid or stains from cigarette use produces localized yellow discoloration of the skin.

Pruritus

Pruritus is the poorly localized, unpleasant sensation that elicits a desire to scratch. The biologic purpose of pruritus is to provoke scratching in order to remove a pruritogen, a response likely to have originated when most pruritogens were parasites. Pruritus is a common manifestation of urticarial reactions, but it may also be of nonimmunologic origin. Pruritus is the most common dermatologic symptom and can arise from a primary dermatologic condition or may be a symptom of an underlying systemic disease in an estimated 10% to 50% of patients.²⁸ Patients with hepatocellular disease frequently have pruritus, which is mediated by the release of bile acids. In addition, in patients with chronic liver disease and obstructive jaundice, pruritus can be caused by central mechanisms, as suggested by elevated central nervous system (CNS) endogenous opioid concentrations. Pruritus can also be caused by topical exposure to the urticating hairs of *Tarantula* spiders, spines of the stinging nettle plant (*Urtica* species), or via stimulation of substance P by certain xenobiotics such as capsaicin.²⁴ Virtually any xenobiotic can cause a cutaneous reaction that can be associated with pruritus whether by inducing hepatotoxicity, cholestasis, phototoxicity, or histamine release (ie, neurologically mediated). Xenobiotics commonly implicated in neurally mediated itch include tramadol, codeine, cocaine, morphine, butorphanol, and methamphetamine.²⁸

Flushing

Vasodilation of the dermal arterioles leads to flushing, or transient reddening of the skin commonly of the face, neck, and chest. Flushing can occur after autonomically mediated vasodilation, as occurs with stress, anger, or exposure to heat, or it can be chemically induced by vasoactive xenobiotics. Xenobiotics that cause histamine release through a type I hypersensitivity reaction are the most frequent cause of xenobiotic-induced flush. Histamine and saurine poisoning can result from the consumption of scombrototoxic fish and can produce flushing. Flushing after the consumption of ethanol is common in patients of Asian and Inuit descent and is similar to the reaction after ethanol consumption in patients exposed to disulfiram or similar xenobiotics (Chap. 79). The increased production of and inability to efficiently metabolize acetaldehyde, the initial metabolite of ethanol, results in the characteristic syndrome of vomiting, headache, and flushing. Niacin causes flushing through an arachidonic acid-mediated pathway that is generally prevented by aspirin.^{7,62} Vancomycin, if too rapidly infused, causes a transient bright red flushing mediated by histamine and at times can be accompanied by hypotension. This reaction typically occurs during and immediately after the infusion, and is termed “red man syndrome.” Idiopathic flushing can be managed with nonselective β -adrenergic antagonists (nadolol, propranolol) or clonidine, and anxiolytics may have benefit if emotional distress or anxiety is evident. Other nontoxicologic causes of flushing, including carcinoid syndrome, pheochromocytoma, mastocytosis, anaphylaxis, medullary carcinoma of the thyroid, pancreatic cancer, menopausal flushing, and renal carcinoma, must be considered as etiologies in a flushed patient.²⁷

Sweating

Xenobiotic-induced diaphoresis may be part of a physiologic response to heat generation or may be pharmacologically mediated after parasympathetic or sympathomimetic xenobiotic use. Because the postsynaptic receptor on the eccrine glands is muscarinic, most muscarinic agonists stimulate sweat production. Sweating occurs after exposure to cholinesterase inhibitors, such as organic phosphorus compounds, but it may also occur with direct-acting muscarinic agonists such as pilocarpine. Alternatively, antimuscarinics, such as belladonna alkaloids and antihistamines, reduce sweating and produce dry skin. Certain xenobiotics, including the anticholinergics glycopyrrolate, propantheline bromide, and botulinum toxin, have proven useful for the treatment of hyperhidrosis. Botulinum toxin A derived from *Clostridium botulinum* temporarily chemodenervates eccrine sweat glands at the neuromuscular junction via inhibition of presynaptic acetylcholine release and is approved by the Food and Drug Administration for the treatment of primary focal axillary hyperhidrosis.²

XENOBIOTIC-INDUCED DYSPIGMENTATION

Cutaneous pigmentary changes can result from the deposition of xenobiotics that can be ingested and carried to the skin by the blood or may permeate the skin from topical applications. Many heavy metals are associated with dyspigmentation. Argyria, a slate-colored discoloration of the skin resulting from the systemic deposition of silver particles in the skin after excessive ingestion, can be localized or widespread. The discoloration tends to be most prominent in areas exposed to sunlight, probably secondary to the fact that silver stimulates melanocyte proliferation. Histologically, fine black granules are found in the BMZ of the sweat glands, blood vessel walls, and DEJ and along the erector pili muscles ([Chap. 101](#)). Gold, which was historically used parenterally in the treatment of rheumatoid arthritis, caused a blue or slate-gray pigmentation often periorbitally known as chrysiasis. The pigmentation is also accentuated in sun-exposed areas, but unlike argyria, sun-protected areas do not histologically demonstrate gold. Also, melanin is not increased in the areas of hyperpigmentation. The hyperpigmentation is probably secondary to the gold itself, but the cause of its distribution pattern remains unknown. Histologically, the gold is found within lysosomes of dermal macrophages and distributed in a perivascular and perieccrine pattern in the dermis. Bismuth produces a characteristic oral finding of the metallic deposition in the gums and tongue known as bismuth lines as well as a blue-gray discoloration of the face, neck, and dorsal hands. Chronic arsenic exposure may be the result of pesticides or contaminated well water, which can cause cutaneous hyperpigmentation with a bronze hue with areas of scattered hypopigmentation that develop from 1 and 20 years after exposure. Lead also deposits in the gums, causing the characteristic “lead lines,” which are the result of subepithelial deposition of lead granules. Intramuscular injection of iron can cause staining of the skin, resulting in pigmentation similar to that seen in tattoos, and iron storage disorders, known as hemochromatosis, can result in a bronze appearance of the skin.²⁰

Medications are also often implicated in dyspigmentation. The tetracycline class antibiotic minocycline is a highly lipid-soluble, yellow crystalline xenobiotic that turns black with oxidation. Minocycline-induced discoloration of the skin can be accompanied by darkening of the nails, sclerae, oral mucosa, thyroid, bones, and teeth. Hyperpigmentation from minocycline is divided into three types depending on the color, anatomic distribution, and whether iron- or melanin-containing granules are found within the skin. Other medications commonly associated with hyperpigmentation include amiodarone, zidovudine, bleomycin and other chemotherapeutics, antimalarials, and psychotropics (chlorpromazine, thioridazine, imipramine, desipramine, amitriptyline).²⁹ Although not true dyspigmentation, as noted earlier, topiramate has been linked to blue pseudoachromhidrosis.¹¹

XENOBIOTIC-INDUCED CUTANEOUS REACTIONS (DRUG REACTIONS)

The skin is one of the most common targets for adverse drug reactions.³ Drug eruptions occur in approximately 2% to 5% of inpatients and in more than 1% of outpatients. Several cutaneous reaction patterns account for the majority of clinical presentations occurring in patients with xenobiotic-induced dermatotoxicity ([Table 18–2](#)). The following drug reactions will be discussed in detail: urticarial drug reactions, erythema multiforme (EM), Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN), fixed drug eruption, and drug-induced hypersensitivity syndrome.

TABLE 18–2. Xenobiotics Commonly Associated with Various Cutaneous Reaction Patterns

Acneiform

ACTH

Amoxapine

Androgens

Azathioprine

Bromides

Corticosteroids

Danazol

Dantrolene

Halogenated hydrocarbons

Iodides

Isoniazid

Lithium

Oral contraceptives

Phenytoin

Alopecia

Anticoagulants

Antineoplastics

Hormones

NSAIDs

Phenytoin

Radiation

Retinoids

Selenium

Thallium

Allergic Contact Dermatitis

Bacitracin

Balsam of Peru

Benzocaine

Carba mix

Catechol

Cobalt

Diazolidinyl urea

Ethylenediamine dihydrochloride

Formaldehyde

Fragrance mix
Imidazolidinyl urea
Lanolin
Methylchloroisothiazolinone or methylisothiazolinone
Neomycin sulfate
Nickel
p-Tert-butylphenol formaldehyde resin
p-Phenylenediamine
Quaternium-15
Rosin (colophony)
Sesquiterpene lactones
Thimerosal
Urushiol

Erythema Multiforme

Antimicrobials
Allopurinol
Barbiturates
Carbamazepine
Cimetidine
Codeine
Gold
Glutethimide
Ethinyl estradiol
Furosemide
Ketoconazole
Methaqualone
NSAIDs
Nitrogen mustard
Phenolphthalein
Phenothiazines
Phenytoin
Sulfonamides

Thiazides

Erythroderma

Allopurinol

Anticonvulsants

Boric acid

Calcium channel blockers

Cimetidine

Dapsone

Gold

Lithium

Penicillins

Quinidine

Sulfonamides

Vancomycin

Fixed Drug Eruption

Acetaminophen

Allopurinol

Barbiturates

Captopril

Carbamazepine

Chloral hydrate

Chlordiazepoxide

Chlorpromazine

Erythromycin

D-Penicillamine

Fiorinal

Gold

Griseofulvin

Lithium

Phenolphthalein

Methaqualone

Metronidazole

Minocycline

Naproxen

NSAIDs

Oral contraceptives

Salicylates

Hair Loss

Telogen Effluvium

β-Adrenergic antagonists (eg, propranolol)

Anticoagulants (especially heparin)

Anticonvulsants (eg, phenytoin, valproic acid, carbamazepine)

Antithyroid (propylthiouracil, methimazole)

Heavy metals

Interferon-α-2b

Oral contraceptives (discontinuation)

Retinoids (acitretin, isotretinoin) and vitamin A excess

Anagen Effluvium

Alkylating agents: cyclophosphamide, ifosfamide, mechlorethamine

Anthracyclines: daunorubicin, doxorubicin, idarubicin

Arsenic

Bismuth

Chemotherapeutics (taxanes: paclitaxel, docetaxel, topoisomerase-inhibitors: topotecan, irinotecan, etoposide, vincristine, vinblastine, busulfan, actinomycin D, gemcitabine)

Gold

Thallium

Maculopapular or Exanthematous Drug Eruption

Antimicrobials

Anticonvulsants

Antihypertensive agents

Photosensitivity Reactions

Amiodarone

Benoxaprofen

Chlorpromazine

Ciprofloxacin

Dacarbazine

5-Fluorouracil

Furosemide

Griseofulvin

Hydrochlorothiazide

Hematoporphyrin (Porphyria)

Levofloxacin

NSAIDS

Oxybenzone

Piroxicam

Psoralen

Sulfanilamide

Tetracyclines

Tolbutamide

Vinblastine

Phototoxic Dermatitis

Celery

Dispense blue 35

Eosin

Fig

Fragrance materials

Lime

Parsnip

Tar

Toxic Epidermal Necrolysis

Allopurinol

L-Asparaginase

Amoxapine

Mithramycin

Nitrofurantoin

NSAIDs

Penicillin

Phenytoin

Prazosin

Pyrimethamine-sulfadoxine

Streptomycin

Sulfonamides

Sulfasalazine

Trimethoprim-sulfamethoxazole

Vasculitis

Allopurinol

Bortezomib

Cephalosporins (commonly Cefaclor)

Cimetidine

G-CSF

Gold

Hydralazine

Levamisole

Methotrexate

Minocycline

NSAIDs

Oral contraceptives

Penicillamine

Penicillin

Phenytoin

Propylthiouracil

Quinolones

Serum (antithymocyte globulin)

Sulfonamides

Vesiculobullous

Amoxapine

Barbiturates

Captopril

Carbon monoxide

Chemotherapeutics

Dipyridamole

Furosemide

Griseofulvin

Penicillamine

Penicillin

Rifampin

Sulfonamides

Xanthoderma

Generalized

Carotenoderma

Canthaxanthin (tanning pills)

Dipyridamole (yellow compound)

Hepatic jaundice (acetaminophen, isoniazid)

Hemolytic jaundice

Quinacrine

Localized

Dihydroxyacetone (spray tanning)

Picric acid

Methylenedianiline

Phenol, topical

Nail Changes: Beau Lines and Mees Lines (Leukonychia)

Arsenic

Cyclophosphamide

Doxorubicin

Hydroxyurea

Paclitaxel

Thallium

ACTH = adrenocorticotrophic hormone; G-CSF = granulocyte colony-stimulating factor; NSAID = nonsteroidal antiinflammatory drug.

Urticarial Drug Reactions

Urticarial drug reactions are characterized by transient, pruritic, edematous, pink papules, or wheals that arise in the dermis, which blanch on palpation and are frequently associated with central clearing. At times the urticarial lesions can be targetoid and mimic EM. Approximately 40% of patients with urticaria experience angioedema and anaphylactoid reactions

as well.¹ The reaction pattern is representative of a type I, or IgE-dependent, immune reaction and commonly occurs as part of clinical anaphylaxis or anaphylactoid (non-IgE-mediated) reactions. Widespread urticaria may occur after systemic absorption of an allergen or after a minimal localized exposure in patients highly sensitized to the allergen. After limited exposure, a localized form of urticaria may occur. Regardless of the specific clinical presentation, the reaction occurs as a result of immunologic recognition of a putative antigen by IgE antibodies, thus triggering the immediate degranulation of mast cells, which are distributed along the dermal blood vessels and nerves. The release of histamine, complements C3a and C5a, and other vasoactive mediators results in extravasation of fluid from dermal capillaries as their endothelial cells contract. This produces the characteristic urticarial lesions described earlier. Activation of the nearby sensory neurons produces pruritus. Nonimmunologically mediated mast cell degranulation producing an identical urticarial syndrome may also occur after exposure to any xenobiotic.¹⁴

Erythema Multiforme

Historically, it was believed that EM existed on a spectrum with SJS and TEN given overlapping clinical features and morphology; however, these entities have been reclassified on the basis that most cases of EM are believed to be triggered by viral infection (herpes simplex virus most commonly) and most cases of SJS/TEN are triggered by xenobiotics.⁴⁹ EM is an acute self-limited disease characterized by target-shaped, erythematous macules and patches on the palms and soles, as well as the trunk and extremities (Fig. 18–3). The Nikolsky sign, defined as sloughing of the epidermis when direct pressure is exerted on the skin, is absent. Mucosal involvement is absent or mild in EM minor and severe in EM major. Although less common than viral-induced EM, xenobiotics such as sulfonamides, phenytoin, antihistamines, many antibiotics, rosewood, and urushiol can elicit EM. Differentiating EM from SJS/TEN, which can also present with targetoid lesions, can be difficult, especially in the case of bullous EM, and biopsy may be required.

FIGURE 18–3. Erythema multiforme: typical targetoid macules on the palm. (Reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, et al: *Fitzpatrick’s Dermatology in General Medicine*. 8th ed. New York: McGraw-Hill; 2012. Fig. 39–3.)

Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

Toxic epidermal necrolysis and SJS (Fig. 18–4) are considered to be related disorders that belong to a spectrum of increasingly severe skin eruptions.⁴³ SJS is defined by less than 10% body surface area epidermal detachment, SJS–TEN overlap is defined by 10% to 30% involvement, and TEN is defined by more than 30% epidermal sloughing. Although on a spectrum, SJS has a mortality rate of 5%, far lower than the approximately 25% to 50% mortality rate for TEN.^{47,50} TEN is a rare, life-threatening dermatologic emergency whose incidence is estimated at 0.4 to 1.2 cases per 1 million persons, and xenobiotics are causally implicated in 80% to 95% of the cases. More than 220 xenobiotics are implicated in causing TEN. The largest study examining medication triggers of TEN divided these medications into long-term (used for months to years) and short-term ones. Short-term xenobiotics most commonly implicated in the development of TEN included

trimethoprim–sulfamethoxazole and other sulfonamide antibiotics followed by cephalosporins, quinolones, and aminopenicillins.⁵¹ With chronic medication use, the increased risk largely occurred during the first 2 months of treatment and was greatest for carbamazepine, phenobarbital, phenytoin, valproic acid, oxicam NSAIDs, allopurinol, and corticosteroids.

FIGURE 18–4. Toxic epidermal necrolysis. (A) Early eruption. Erythematous dusky red macules (flat atypical target lesions) that progressively coalesce and show epidermal detachment. (B) Advanced eruption. Blisters and epidermal detachment have led to large, confluent erosions. (C) Full-blown epidermal necrolysis characterized by large erosive areas reminiscent of scalding. (Reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, et al: *Fitzpatrick’s Dermatology in General Medicine*. 8th ed. New York: McGraw-Hill; 2012.)

Classically, the eruption of TEN is painful and occurs within 1 to 3 weeks of the exposure to the implicated xenobiotic(s). The eruption is preceded by malaise, headache, abrupt onset of fever, myalgia, arthralgia, nausea, vomiting, diarrhea, chest pain, or cough. About 1 to 3 days later, signs begin in the mucous membranes, including the eyes, mouth, nose, and genitals in 90% of cases.⁴⁷ Next a macular erythema develops that subsequently becomes raised and morbilliform on the face, neck, and central trunk, which then progresses to involve the extremities. Individual lesions may appear targetoid because of their dusky centers and progress to bullae in the next 3 to 5 days involving the entire thickness of the epidermis. The nails may be involved becoming necrotic and can slough off. A Nikolsky sign may occur, and although suggestive, is not pathognomonic of TEN because it occurs in a variety of other dermatoses, including pemphigus vulgaris. If the diagnosis is suspected, a punch biopsy should be performed for immediate frozen section and the suspected triggering xenobiotic discontinued immediately. The histopathology typically shows partial or full-thickness epidermal necrosis, with subepidermal bullae with a sparse infiltrate and vacuolization with numerous dyskeratotic keratinocytes along the DEJ adjacent to the necrotic epidermis.

The incidence of TEN is higher in patients with advanced HIV disease.^{43,59} There is general agreement that the keratinocyte cell death in TEN is the result of apoptosis, which is suggested based on electronic microscopic studies with DNA fragmentation analysis.⁴³ Cytotoxic T lymphocytes are the main effector cells, and experimental evidence points to involvement of the Fas-ligand (FasL) and perforin–granzyme pathways. There are several theories as to the pathogenesis of SJS/TEN. These include that a xenobiotic might induce upregulation of FasL by keratinocytes constitutively expressing Fas, leading to a death receptor–mediated apoptotic pathway; the xenobiotic might interact with major histocompatibility class I–expressing cells, and then drug-specific CD8⁺ cytotoxic T lymphocytes accumulate within epidermal blisters, releasing perforin and granzyme B that kill keratinocytes; or that the xenobiotic may also trigger the activation of CD8⁺ T lymphocytes and natural killer (NK) cells, to secrete granulysin, with keratinocyte death not requiring cell contact.⁴² Serum FasL concentrations are elevated up to 4 days before mucosal involvement in patients with SJS/TEN and may become useful clinically because an early predictor of these severe dermatologic diseases.⁴¹ Serum granulysin, a proinflammatory cytolytic enzyme released by CD8⁺ T lymphocytes found in the blisters of TEN, has been investigated as a potential early predictive marker of SJS/TEN.¹⁹ A rapid immunochromatographic test that detects elevated serum granulysin (>10 ng/mL) in 15 minutes has shown promise in a small study in which its sensitivity was noted to be 80% and specificity 95.8% for differentiating SJS/TEN from ordinary exanthematous drug eruptions.¹⁹ However, this test is not yet commercially available.

Because immediate removal of the inciting xenobiotic is critical to survival, patients with TEN related to a xenobiotic with a long half-life have a poorer prognosis and should be transferred to a burn or other specialized center for sterile wound care. Risk factors for mortality, such as age, extent of epidermal detachment, and base deficit, have been proposed.

In a recent study, only serum bicarbonate concentration less than 20 mEq/L was found to portend hospital death in patients with TEN.⁶⁴ Porcine xenografts or human skin allografts, including amniotic membrane transplantation, are used and are widely accepted therapies.⁴⁶ Although corticosteroids are not generally recommended, there is emerging support for the use of intravenous immunoglobulin (IVIG), cyclophosphamide, and cyclosporine.⁴⁶ A large meta-analysis of 17 studies revealed a trend toward improved mortality with high-dose IVIG in adults and good prognosis in children; however, the authors concluded that there was no significant evidence to support a clinical benefit, so this treatment remains controversial.²⁶ Patients with TEN may develop metabolic abnormalities, sepsis, multiorgan failure, pulmonary emboli, and GI hemorrhages. The major microbes leading to sepsis are *Staphylococcus aureus* and *Pseudomonas aeruginosa*. In a patient with SJS/TEN with ophthalmic involvement early ophthalmologic consultation is necessary because blindness is a potential complication.

Mimickers of TEN include SJS, staphylococcal scalded skin syndrome, severe exanthematous drug eruptions, EM major, linear IgA dermatosis, paraneoplastic pemphigus, acute graft-versus-host disease, drug-induced pemphigoid, pemphigus vulgaris, and acute generalized exanthematous pustulosis; however, discussion of some of these entities is beyond the scope of this chapter (Table 18–3).

Bullous Reactions (Blistering Reactions)

In addition to SJS and TEN, other bullous cutaneous reactions include drug-induced pseudoporphyria, fixed drug eruption, acute generalized exanthematous pustulosis, phototoxic drug eruptions, and drug-induced autoimmune blistering diseases. Xenobiotic-related cutaneous blistering reactions may be clinically indistinguishable from autoimmune blistering diseases such as pemphigus vulgaris or bullous pemphigoid (Fig. 18–5). Certain topically applied xenobiotics such as the vesicant cantharidin derived from “blister beetles” in the Coleoptera order and Meloidae family are used in the treatment of molluscum and viral warts. In high concentrations, xenobiotics can lead to necrosis of both skin and mucous membranes. Other systemic xenobiotics cause a similar reaction pattern mediated by the production of antibody directed against the cells at the DEJ (Table 18–3).

FIGURE 18–5. Pemphigus vulgaris. (A) Flaccid blisters. (B) Oral erosions. (Part A used with permission of Lawrence Lieblisch, MD. Part B reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, et al: Fitzpatrick’s Dermatology in General Medicine. 8th ed. New York: McGraw-Hill; 2012.)

TABLE 18–3. Differential Diagnosis of Xenobiotic-Induced Blistering (Vesiculobullous) Disorders

<i>Disease</i>	<i>Fever</i>	<i>Mucositis</i>	<i>Morphology</i>	<i>Onset</i>	<i>Miscellaneous</i>
Xenobiotic-induced pemphigoid	No	Rare	Tense bullae (sometimes hemorrhagic)	Acute	Diuretics a common cause, especially furosemide, spironolactone; often pruritic
Staphylococcal scalded skin syndrome	Yes	Absent	Erythema, skin tenderness, periorificial crusting	Acute	Affects children younger than 5 years, adults on dialysis, and those on immunosuppressive therapy
Xenobiotic-induced pemphigus	No	Usually absent	Erosions, crusts, patchy erythema (resembles pemphigus foliaceus)	Gradual	Commonly caused by penicillamine and other "thiol" drugs; often resolves after inciting agent is discontinued
Xenobiotic-triggered pemphigus	No	Present	Mucosal erosions, flaccid bullae	Gradual	Caused by "nonthiol" drugs; more likely to persist after discontinuation of drug; may require long-term immunosuppressive therapy
Paraneoplastic pemphigus	No	Present (usually severe)	Polymorphous skin lesions, flaccid bullae	Gradual	Resistant to treatment; associated with malignancy, especially lymphoma
Acute graft-versus-host disease	Yes	Present	Morbilloform rash, bullae and erosions	Acute	Closely resembles toxic epidermal necrolysis
Acute generalized exanthematous pustulosis	Yes	Rare	Superficial pustules	Acute	Self-limiting on discontinuation of drug
Xenobiotic-induced linear IgA bullous dermatosis	No	Rare	Tense, subepidermal bullae	Acute	Vancomycin is most commonly implicated

A number of medications, many of which contain a “thiol group” such as penicillamine and captopril, can induce either pemphigus resembling pemphigus foliaceus, a superficial blistering disorder in which the blister is at the level of the stratum granulosum, or pemphigus vulgaris, in which blistering occurs above the basal layer of the epidermis (Fig. 18–1). Other xenobiotics, such as furosemide, penicillin, and sulfasalazine, produce tense bullae that resemble bullous pemphigoid. Direct immunofluorescence studies might show epidermal intracellular immunoglobulin deposits at the DEJ. Treatment options include stopping the offending xenobiotic and at times treating with immunosuppressants used to treat bullous pemphigoid and pemphigus vulgaris. The reaction may persist for up to 6 months after the offending xenobiotic is withdrawn.

Fixed Drug Eruption. Fixed drug eruption is another bullous drug eruption that is characterized by well-circumscribed erythematous to dusky violaceous patches that may have central bullae or erosions and develops 1 to 2 weeks after first exposure to the drug. This reaction pattern is so named because reexposure to the xenobiotic causes lesions in the same area but typically within 24 hours of exposures (Fig. 18–6). Typical locations include the acral extremities, genitals, and intertriginous sites, and this process may be confused with TEN if widely confluent as in “generalized fixed drug eruption.” This reaction pattern is generally not life threatening and heals with residual postinflammatory hyperpigmentation. Bullous fixed-drug reactions result from exposure to diverse xenobiotics such as angiotensin-converting enzyme inhibitors and a multitude of antibiotics. As mentioned earlier, EM can have a bullous variant that can also be confused with SJS/TEN.

FIGURE 18–6. Fixed drug eruption caused by tetracycline. A well-defined plaque on the knee merging with three satellite lesions. The large plaque exhibits epidermal wrinkling, a sign of incipient blister formation. This was the second such episode after ingestion of a tetracycline. No other lesions were present. (Reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, et al: *Fitzpatrick's Dermatology in General Medicine*. 8th ed. New York: McGraw-Hill; 2012.)

Coma Bullae. “Coma bullae” are tense bullae on normal appearing skin that occur within 48 to 72 hours in comatose patients with sedative–hypnotic overdoses, particularly phenobarbital, or carbon monoxide poisoning. They may also be seen in patients in coma from infectious, neurologic, or metabolic causes. Although these blisters are thought to result predominantly from pressure-induced epidermal necrosis, they occasionally occur in non–pressure-dependent areas, suggesting a systemic mechanism. Histologically, an intraepidermal or subepidermal blister may be observed. There is accompanying eccrine duct and gland necrosis.

Drug-Induced Hypersensitivity Syndrome

The drug hypersensitivity syndrome, also called drug reaction with eosinophilia and systemic symptoms (DRESS), can be severe and potentially life threatening. The skin may be involved with systemic immunologic diseases such that an alteration in the metabolism of certain xenobiotics leads to a hypersensitivity syndrome. The hypersensitivity syndrome is characterized by the triad of fever, skin eruption, and internal organ involvement.³¹ The frequency has been estimated between one in 1000 to one in 10,000 with anticonvulsants or sulfonamide antibiotic exposures and usually begins within 2 to 6 weeks after the initial exposure. For anticonvulsants, the inability to detoxify arene oxide metabolites has been suggested to be a key factor; after a patient has a documented drug-induced hypersensitivity syndrome to one anticonvulsant, it is important to note that cross-reactivity between phenytoin, carbamazepine, and phenobarbital is well documented, both in vivo and in vitro.⁴⁵ In the case of sulfonamides, acetylator phenotype and lymphocyte susceptibility to the metabolite hydroxylamine are risk factors for developing drug hypersensitivity syndrome. Further support for the role of genetic predisposition comes from data in Northern European populations in which the presence of the HLA-A*3101 allele significantly increases the risk of developing carbamazepine-induced hypersensitivity syndrome.³³ Fever and a cutaneous eruption are the most common symptoms. Accompanying malaise, pharyngitis, and cervical lymphadenopathy may also be present. Atypical lymphocytes and eosinophilia occur initially. The exanthem is initially generalized and morbilliform, and conjunctivitis and angioedema may occur (Fig. 18–7). Later the eruption becomes edematous and facial edema, which is often present, is a hallmark of this syndrome. Half of patients with drug-induced hypersensitivity syndrome will have hepatitis, interstitial nephritis, vasculitis, CNS manifestations (including encephalitis, aseptic meningitis), interstitial pneumonitis, acute respiratory distress syndrome, and autoimmune hypothyroidism. Hepatic involvement can be fulminant and is the most common cause of death associated with this syndrome. Colitis with bloody diarrhea and abdominal pain may occur. In addition to the aromatic anticonvulsants (phenobarbital, carbamazepine, and phenytoin), lamotrigine, allopurinol, sulfonamide antibiotics, dapsone, and the protease inhibitor abacavir have been implicated. Early withdrawal of the offending xenobiotic is crucial, and treatment is generally supportive.^{40,63} If cardiac or pulmonary involvement is present, systemic corticosteroids are often recommended; however, their benefit on outcome has not been demonstrated, and relapse may occur during tapering, necessitating long-term courses of therapy.

FIGURE 18–7. A patient with a hypersensitivity syndrome associated with phenytoin. He has a symmetric, bright red, exanthematous eruption, confluent in some sites. The patient had associated lymphadenopathy. (Reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, et al: *Fitzpatrick's Dermatology in General Medicine*. 8th ed. New York: McGraw-Hill; 2012.)

Erythroderma

Erythroderma, also known as exfoliative dermatitis, is defined as a generalized redness and scaling of the skin. However, it does not represent one disease entity; rather, it is a severe clinical presentation of a variety of skin diseases, including psoriasis, atopic dermatitis, drug reactions, or cutaneous T-cell lymphoma (CTCL). At times the underlying etiology of erythroderma is never discovered, and this is termed “idiopathic erythroderma.” The importance of this presentation is its association with systemic complications such as hypothermia; peripheral edema; and loss of fluid, electrolytes, and albumin with subsequent tachycardia and cardiac failure. Many xenobiotics can lead to erythroderma ([Table 18–2](#)). When ingested, boric acid can cause systemic toxicity in addition to a bright red eruption (“lobster skin”) usually followed within 1 to 3 days by a generalized exfoliation.⁵³

Vasculitis

Xenobiotic-induced vasculitis ([Fig. 18–8](#)) comprises 10% to 15% of secondary cutaneous vasculitis. It generally occurs from 7 to 21 days after initial exposure to the xenobiotic or 3 days after rechallenge and is considered to be a secondary cause of cutaneous small vessel vasculitis (typically involving dermal postcapillary venules). Many xenobiotics are implicated as triggers of cutaneous vasculitis ([Table 18–2](#)).⁵⁷ Cutaneous vasculitis is characterized by purpuric, nonblanching macules that usually become raised and palpable. The purpura tends to occur predominantly on gravity-dependent areas, including the lower extremities, particularly the feet, ankles, and buttocks. Sometimes the reaction pattern can have edematous purpuric wheals (urticarial vasculitis), hemorrhagic bullae, or ulcerations. The underlying histopathology shows a leukocytoclastic vasculitis, which is characterized by fibrin deposition in the vessel walls. There is a perivascular infiltrate with intact and fragmented neutrophils that appear as black dots, known as “nuclear dust,” and extravasated red blood cells. This reaction pattern may be limited to the skin or may be more serious and involve other organ systems, particularly the kidneys, joints, liver, lungs, and brain. The purpura results from the deposition of circulating immune complexes, which form as a result of a hypersensitivity to a xenobiotic. Treatment consists of withdrawing the putative xenobiotic and systemic corticosteroid therapy if systemic involvement is present. A syndrome of vasculitis, neutropenia, and retiform purpura has been reported as a result of levamisole-adulterated cocaine.¹³ The earlobe is a common site of purpuric lesions from levamisole, and it is estimated that up to 70% of the cocaine and less than 3% of the heroin supply in the United States contained levamisole.^{6,60,61}

FIGURE 18–8. Leukocytoclastic vasculitis in a patient with mixed cryoglobulinemia manifested as palpable purpura and acrocyanosis. The patient had tuberculosis, positive antinuclear antibody, and hepatitis. (Reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, et al: *Fitzpatrick's Dermatology in General Medicine*. 8th ed. New York: McGraw-Hill; 2012.)

Purpura. Purpura is the multifocal extravasation of blood into the skin or mucous membranes ([Fig. 18–9](#)). Ecchymoses are therefore considered to be purpuric lesions. Cytotoxic medications that either diffusely suppress the bone marrow or specifically depress platelet counts below 30,000/mm³ predispose to purpuric macules. Xenobiotics that interfere with platelet aggregation, such as aspirin, clopidogrel, ticlopidine, and valproic acid, may cause purpura, as may thrombolytics. Anticoagulants, such as heparin and warfarin, may also result in purpura ([Chaps. 22](#) and [60](#)).

FIGURE 18–9. Purpura. Nonblanching red erythematous papules and plaques (palpable purpura) on the legs representing leukocytoclastic vasculitis. (Reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, et al: *Fitzpatrick's Dermatology in General Medicine*. 8th ed. New York: McGraw-Hill; 2012.)

Anticoagulant-Induced Skin Necrosis. Skin necrosis from warfarin, low-molecular-weight heparin, or unfractionated heparin usually begins 3 to 5 days after the initiation of treatment, which corresponds with the expected early decline of protein C function with warfarin ([Fig. 18–10](#)). The estimated risk is one in 10,000 persons. It is four times higher in women, especially if they are obese, with peaks in the sixth to seventh decades of life. The necrosis is secondary to thrombus formation in vessels of the dermis and subcutaneous fat. Heparin-induced cutaneous necrosis results from antibodies that bind to complexes of heparin and platelet factor 4 and induce platelet aggregation and consumption. There

may be bullae, ecchymosis, ulcers, and massive subcutaneous necrosis, usually in areas of abundant subcutaneous fat, such as the breasts, buttocks, abdomen, thighs, and calves. It may be associated with protein C or S deficiency, anticardiolipin antibody syndrome, and factor V Leiden mutations.⁴⁴ Treatment involves discontinuing the medication; administration of vitamin K; and, if warfarin induced, switching to heparin. Treatment may include fresh-frozen plasma and protein C. Skin grafting may be necessary if full-thickness necrosis occurs.

FIGURE 18–10. Skin necrosis in a patient after 4 days of warfarin therapy. (Reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, et al: *Fitzpatrick's Dermatology in General Medicine*. 8th ed. New York: McGraw-Hill; 2012.)

Contact Dermatitis

When a xenobiotic comes in contact with the skin, it can result in either an allergic contact dermatitis (20% of cases) or more commonly an irritant contact dermatitis (80% of cases). Contact dermatitis is characterized by inflammation of the skin with spongiosis (intercellular edema) of the epidermis that results from the interaction of a xenobiotic with the skin. Well-demarcated erythematous vesicular or scaly patches or plaques may be noted on areas in direct contact with the xenobiotic while the remaining areas are spared. Bullae may be present.

Allergic contact dermatitis fits into the classic delayed hypersensitivity, or type IV, immunologic reaction. The development of this reaction requires prior sensitization to an allergen, which, in most cases, acts as a hapten by binding with an endogenous molecule that is then presented to an appropriate immunologic T cell. Upon reexposure, the hapten diffuses to the Langerhans cell, is chemically altered, and bound to an HLA-DR, and the complex is expressed on the Langerhans cell surface. This complex interacts with primed T cells either in the skin or lymph nodes, causing the Langerhans cells to make interleukin-1 and the activated T cells to make interleukin-2 and interferon. This subsequently activates the keratinocytes to produce cytokines and eicosanoids that activate mast cells and macrophages, leading to an inflammatory response (Fig. 18–11).³⁰

FIGURE 18–11. Contact dermatitis. (1) Causative xenobiotic, typically a hapten of less than 500 Da diffuses through the stratum corneum and binds to receptor on Langerhans cell (LC). (2) The antigen is processed with major histocompatibility complex II (MHC II) receptor site, presented to T-helper lymphocytes, and carried through the lymphatics to regional lymph nodes. (3) There it undergoes the sensitization phase by producing memory, effector, and suppressor T lymphocytes. (4) On reexposure to the same or to a cross-reactive antigen, the LC represents the antigen to T lymphocytes (----->), which are now sensitized. This initiates an inflammatory process that appears as indurated, scaly patches.

Many allergens are associated with contact dermatitis; a complete list is beyond the scope of this chapter. However, some common xenobiotics are listed in [Table 18–2](#). Among the most common plant-derived sensitizers are urushiol (*Toxicodendron* species), sesquiterpene lactone (ragweed), and tuliposide A (tulip bulbs). Metals, particularly nickel, are commonly implicated in contact dermatitis and should be considered in patients with erythematous, vesicular or scaly patches or plaques around the umbilicus from nickel buttons on pants, and on the ear lobes from earrings. Several industrial chemicals, such as the thiurams (rubber) and urea formaldehyde resins (plastics), account for the majority of occupational contact dermatitis. Medications, particularly topical medications such as neomycin, commonly cause contact dermatitis. An important allergen that is becoming more frequent is paraphenylenediamine (PPD), a black dye in permanent and semipermanent hair coloring, leather, fur, textiles, industrial rubber products, and black henna tattoos. According to the North American Contact Dermatitis Group, the frequency of sensitization to PPD has been found to be 5.0%.⁶⁵ Management strategies commonly used are outlined in [Table 18–4](#). A thorough history in addition to patch testing (the gold standard) will often identify the culprit.

TABLE 18–4. Overview of Treatment of Acute Contact Dermatitis

Identification of contactant and future avoidance
Drying agents, such as topical aluminum sulfate or calcium acetate: if weeping
Emollients: lichenified lesions
Corticosteroids, topical, rarely systemic: for severe reactions
Calcineurin inhibitors (tacrolimus or pimecrolimus)
Cyclosporine (oral)
Phototherapy, ultraviolet A or B

Irritant dermatitis, although clinically indistinguishable from direct damage to the skin and does not require prior antigen sensitization. Still, the inflammatory response to the initial mild insult is the cause of the majority of the damage. Irritant xenobiotics include acids, bases, solvents, and detergents, many of which, in their concentrated form or after prolonged exposure, can cause direct cellular injury. The specific site of damage varies with the chemical nature of the xenobiotic. Many xenobiotics can affect the lipid membrane of the keratinocyte, but others can diffuse through the membrane, injuring the lysosomes, mitochondria, or nuclear components. When the cell membrane is injured, phospholipases are activated and affect the release of arachidonic acid and the synthesis of eicosanoids. The second-

messenger system is then activated, leading to the expression of genes and the synthesis of various cell surface molecules and cytokines. Interleukin-1 is secreted, which can activate T cells directly and indirectly by stimulation of granulocyte-macrophage colony-stimulating factor production. Treatment is similar to allergic contact dermatitis.

Photosensitivity Reactions

Photosensitivity may be caused by topical or systemic xenobiotics. Nonionizing radiation, particularly to ultraviolet A (UVA) (320–400 nm) and less often to ultraviolet B (UVB) (280–320 nm), are the wavelengths that commonly cause photosensitivity. There are generally two types of xenobiotic-related photosensitivities, phototoxic and photoallergic.³⁹ Phototoxic reactions occur within 24 hours of the first exposure, usually within hours, and are dose related. These reactions result from direct tissue injury caused by UV-induced activation of a phototoxic xenobiotic. The clinical findings include erythema, edema, and vesicles in a light-exposed distribution and resemble a severe sunburn that can last for days to weeks with patients complaining of burning and stinging (Fig. 18–12). A subtype of phototoxic reaction includes phytophotodermatitis in which linear streaks of erythema occur after skin contact with furocoumarins from plants plus exposure to sunlight (Table 18–2). Photoallergic reactions occur less commonly, may occur after even small exposures, and resemble allergic contact dermatitis with lichenoid papules or an eczematous dermatitis on exposed areas and is often pruritic. These are type IV hypersensitivity reactions that develop in response to a xenobiotic that has been altered by absorption of nonionizing radiation, acting as a hapten and eliciting an immune response on first exposure. Only on recurrent exposure do the lesions develop. Studies indicate that benzophenone-3 (oxybenzone), often found in sunscreen, is the most common cause of photoallergic dermatitis.^{8,16} Other common photoallergens include xenobiotics such as promethazine, NSAIDs, fragrances, and antibacterial agents. Photoallergic reactions can be diagnosed by the use of photopatch tests. Both phototoxic and photoallergic reactions are managed with symptomatic treatment, including topical or, if needed, systemic corticosteroids. Identification and avoidance of the triggering xenobiotic are crucial in addition to avoidance of sun exposure and wearing a broad-spectrum sunscreen (SPF 30 or above) that blocks both UVA and UVB preferably without para-aminobenzoic acid (PABA). PABA is a sensitizing agent to many patients and is rarely included in current sunscreen products.

FIGURE 18–12. Phototoxicity associated with a heterocyclic antidepressant. Note the erythema and edema on sun-exposed areas and sparing of sun-protected chest and shaded upper lip and neck. (Photo contributed by Dr. Adrian Tanew. Reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, et al: *Fitzpatrick's Dermatology in General Medicine*. 7th ed. New York: McGraw-Hill; 2008.)

Sclerodermalike Reactions

A number of environmental xenobiotics are associated with localized or diffuse sclerodermalike reactions. Sclerodermatous refers to a tightened, indurated surface change of the skin that typically occurs on the face, hands, forearms, and trunk and is three times more common in women. This may be accompanied by facial telangiectasias and Raynaud syndrome. Raynaud syndrome consists of skin color changes of white, blue, and red accompanied by intense pain

with exposure to cold and can cause acral ulcerations if left untreated. The fibrotic process usually does not remit with removal of the external stimulus, and specific autoantibodies are absent. The association of scleroderma-like reactions with polyvinyl chloride manufacture is likely related to exposure to vinyl chloride monomer. Similar reports of this syndrome are associated with exposure to trichloroethylene and perchloroethylene, which are structurally similar to vinyl chloride. Epoxy resins, silica, and organic solvents have been implicated as environmental causes. The xenobiotics bleomycin, carbidopa, pentazocine, and taxanes are causative.

In Spain, patients exposed to imported rapeseed oil mixed with an aniline denaturant developed widespread cutaneous sclerosis. This became known as the “toxic oil syndrome.” A similar syndrome, after ingestion of contaminated L-tryptophan as a dietary supplement used as a sleeping aid, resulted in the eosinophilia myalgia syndrome, which is characterized by myalgia, paralysis, edema, arthralgias, alopecia, urticaria, mucinous yellow papules, and erythematous plaques.⁵⁴

Hair Loss

Xenobiotics have the potential to cause distinctive patterns of hair loss (Table 18–2). Anagen effluvium, or hair loss during the anagen stage of the growth cycle, is caused by interruption of the rapidly dividing cells of the hair matrix, producing rapid hair loss within 2 to 4 weeks. Telogen effluvium, or toxicity during the resting stage of the cycle, typically produces hair loss 2 to 4 months later and occurs as a side effect of medication or in the setting of systemic disease or altered physiologic states (eg, postpartum). Anagen toxicity is commonly associated with xenobiotic exposures such as to doxorubicin, cyclophosphamide, vincristine, and thallium.⁵⁶ Many antineoplastics reduce the mitotic activity of the rapidly dividing hair matrix cells, leading to the formation of a thin, easily breakable shaft. Thallium, a toxin classically associated with hair loss, causes alopecia by two mechanisms. Thallium distributes intracellularly, similar to potassium, altering potassium-mediated processes and thereby disrupting protein synthesis. By binding sulfhydryl groups, thallium also inhibits the normal incorporation of cysteine into keratin. Thallium toxicity results in alopecia 1 to 4 weeks after exposure. Within 4 days of exposure, a hair mount observed using light microscopy will demonstrate tapered or bayonet anagen hair with a characteristic bandlike black pigmentation at the base. Seeing this anagen effect can reveal the timing of exposure (Chap. 102). Soluble barium salts, such as barium sulfide, are applied topically as a depilatory to produce localized hair loss. The mechanism of hair loss is undefined.

Nails

The nail consists of a horny layer the “nail plate” and four specialized epithelia: proximal nail fold, nail matrix, nailbed, and hyponychium. The nail matrix consists of keratinocytes, melanocytes, Langerhans cells, and Merkel cells.

Nail hyperpigmentation occurs for unclear reasons but may be caused by focal stimulation of melanocytes in the nail matrix leading to melanonychia. The pigment deposition can be longitudinal, diffuse, or perilar in orientation and typically develops several weeks after chemotherapy.⁵⁶ Black dark-skinned patients are more commonly affected because of a higher concentration of melanocytes. Cyclophosphamide, doxorubicin, hydroxyurea, zidovudine, and bleomycin are among the most common xenobiotics that cause melanonychia, and the pigmentation generally resolves with cessation of therapy. When approaching a patient with a single streak of longitudinal melanonychia, it is crucial to include nail melanoma in the differential diagnosis.

Nail findings may serve as important clues to xenobiotic exposures that have occurred in the recent past. Matrix keratinization, in a programmed and scheduled pattern, leads to the formation of the nail plate. Certain changes in nails, such as Mees and Beau lines, result from a temporary arrest of the proximal nail matrix proliferation. These lines can be used to predict the timing of a toxic exposure because of the reliability of rate of growth of the nails at approximately 0.1 mm/d. Mees lines, first described in 1919 in the setting of arsenic poisoning, can be used to approximate the date of the insult by the position of growth of the Mees line a patterned leukonychia (not indentation) causing transverse white lines.³⁴ Multiple Mees lines suggest multiple exposures over time. Arsenic, thallium, doxorubicin, vincristine, cyclophosphamide, methotrexate, and 5-fluorouracil are examples of xenobiotics that cause Mees lines, but Mees lines may be noted after any period of critical illness such as sepsis or trauma. Beau lines are transverse grooves or indentations more often in the central portion of the nail plate, most commonly caused by trauma (eg, manicures) or dermatologic disease affecting the proximal nailfold. Beau lines present on multiple digits, especially at the same level on each nail, indicate a systemic illness or xenobiotic exposure (Fig. 18–13).

FIGURE 18–13. Presence of proximal indented Beau line and distal band of leukonychia caused by cyclophosphamide seen 3 months after bone marrow transplantation. (Reproduced, with permission, from Wolff K, Goldsmith LA, Katz SI, et al: *Fitzpatrick's Dermatology in General Medicine*. 8th ed. New York: McGraw-Hill; 2012.)

SUMMARY

- The integument is constantly exposed to both topical and systemic xenobiotics, and these exposures may result in reactive dermatoses.
- Prompt examination of the skin, hair, and nails can provide invaluable clues about the route and nature of the offending xenobiotic.
- A careful history, clinical examination, and consultation with a dermatologist and biopsy when indicated can aid in identifying the etiology and nature of the reaction and lead to prompt treatment.

SC1 SPECIAL CONSIDERATIONS

Transdermal Toxicology

Lewis S. Nelson

HISTORY AND CURRENT USE

Applying a xenobiotic to the skin to treat a systemic medical condition is not new. Ointments and other salves have been applied topically for thousands of years for the treatment of local and systemic diseases. During World War I, dynamite workers used nitroglycerin applied to their hatbands to prevent angina when they were away from work and no longer exposed to organic nitrates.³¹ Mustard seed plaster for chest congestion, releasing allyl isothiocyanate, and topical elemental mercurials for syphilis are other examples from the early 20th century.²⁴ Over the past 30 years, an increasing number of medications have been formulated in transdermal delivery systems or patches to allow for systemic delivery of a xenobiotic. The first commercially available patch delivered scopolamine for motion sickness (1979), which was followed by nitroglycerin for chronic angina (1981) and then fentanyl for chronic pain management (1990). In the United States, the nicotine patch remains the most widely used transdermal delivery system both because of the high need for smoking cessation and its nonprescription availability. Certain medicinal xenobiotics, such as testosterone, can be administered topically without a patch as a spray or gel.¹⁸ Furthermore, nonmedicinals can be absorbed transdermally, as occurs with nicotine after direct exposure to moist tobacco leaf in patient with “green tobacco sickness” or with organic phosphorus pesticides.³

The skin is the largest organ in the body, although it is not generally used as a route for intentional xenobiotic delivery. However, there are several benefits of transdermal delivery of systemic medication. This route provides a noninvasive means to discreetly administer medications. Patches result in steady serum concentrations that reduce side effects particularly for xenobiotics with short half-lives. The patches can be left in place for long periods of time, which improves compliance. Importantly, the avoidance of first-pass metabolism permits a means to effectively deliver poorly orally bioavailable xenobiotics. However, because all absorption through the skin is passive, there is a large degree of variability among both patients and xenobiotics.

This chapter does not cover xenobiotics applied to the skin to produce an effect locally. These xenobiotics can be available in patch formulation (eg, lidocaine and capsaicin) or as a directly applied preparation, such as a variety of antibiotics or acne creams. Locally acting formulations (eg, lidocaine) typically provides only trivial amounts of systemic xenobiotic;⁶ with tretinoin, despite devastating fetal complication when taken orally, these same effects do not occur when applied topically.¹⁶

TRANSDERMAL ADMINISTRATION PHARMACOLOGY

Passive Administration

The same hydrophobic property that allows the skin to prevent water loss hinders the ability to administer a water-soluble xenobiotic transdermally. To reach the systemic circulation, a xenobiotic applied to the stratum corneum (horny layer) (Fig. 18–1) must initially pass through about a dozen layers of keratinized epidermal cells and then into the dermis. This keratinaceous horny layer is highly impervious to water movement because of the presence of ceramides, fatty acids, and other lipids.⁵ This property both physiologically maintains the ability to lose excess water in dry environments and pathologically is lost in burn victims. For a xenobiotic to partition into the waxy stratum corneum, it must be sufficiently lipid soluble. However, this same xenobiotic must subsequently partition out of the stratum corneum into the aqueous underlying tissue, and this requires sufficient hydrophilicity.²² The ability to partition into these various phases (lipid and water) is described by the octanol:water partition coefficient. These vary widely among xenobiotics. For example, this coefficient and logP for fentanyl (717; 2.53) and nicotine (15; 1.18) suggests sufficient ability to cross the stratum corneum, but morphine (0.7, –0.15) cannot pass through this outer layer.

Fick’s first law can be used to describe xenobiotic permeation across the stratum corneum. In this model, steady-state flux (J) is related to the diffusion coefficient (D) of the xenobiotic based on the thickness of the stratum corneum (h), the partition coefficient (P) between the stratum corneum and the xenobiotic in its vehicle, and the xenobiotic concentration (C) that is applied, which is assumed to be constant. This equation demonstrates the influence of solubility and partition

coefficient of a xenobiotic on diffusion across the stratum corneum. Molecules showing intermediate partition coefficients (log P of 1–3) have adequate solubility within the lipid domains of the stratum corneum to permit diffusion through this domain still having sufficient hydrophilic nature to allow partitioning into the viable tissues of the epidermis.

Permeation enhancers improve absorption by solubilizing the xenobiotic or altering the characteristics of the stratum corneum, effectively increasing the lipid solubility of the xenobiotic.²⁷ Approaches include optimizing the solubility of the xenobiotic or enhancing the properties of the skin itself.⁵ Enhancers include solvents such as ethanol, fatty acids, fatty esters, and surfactants that serve as vehicles to improve the solubility of a xenobiotic in the lipids of the stratum corneum layer.⁵ An alternative means of enhancing lipophilicity is the addition of organic functional groups to create a prodrug that is cleaved after being absorbed.²⁵ This is similar to the significantly enhanced neurotoxicity when dimethylmercury is applied to the skin and compared with methylmercury.²⁰ Additionally, the use of nanoparticles enhances xenobiotic solubility and surface contact area.²⁸

Few xenobiotics have the correct molecular requirements to be able to be systemically delivered by the transdermal route. The upper limit of the molecular weight (MW) of an acceptable xenobiotics is 500 Da (fentanyl is 337 Da), and the xenobiotic must be sufficiently potent to exert its desired effect at concentrations that can reliably be obtained. Although only small quantities, typically less than 2 mg daily, are delivered, the largest nicotine patch delivers 21 mg daily.

As suggested by Fick's law, the ability to cross the dermis is related to the concentration gradient provided by the transdermal delivery apparatus. To allow sufficient delivery, a large amount of xenobiotic is contained in the apparatus to maintain the concentration gradient over time. For example, the 50-μg/h fentanyl patch (which delivers 1.2 mg daily) contains 8.4 mg (8400 μg) of fentanyl in the patch.^{12,31} This excess amount of drug minimizes the fluctuations in delivery over time as the concentration gradient naturally falls during movement of xenobiotic from the patch to the skin. Upon completion of the 3-day use of a fentanyl patch, the amount of fentanyl remaining in a patch ranged from 24% to 85%; at the end of use, 27% to 74% of the contents of a nicotine patch may remain.^{17,24,32} Furthermore, to prevent rapid movement into the skin and maintain a functional concentration gradient, a rate-controlling membrane is present that allows a measured amount of drug to pass per area of skin contact surface.

Applying xenobiotic to broken skin or tissue lacking a stratum corneum, such as the mucosa, results in a substantial increase in its absorption which may be more than five- and more than 30-fold, respectively, for fentanyl.^{11,18} However, because the pharmacokinetics of transmucosal delivery tend to be more predictable than by the transdermal route, certain formulations such as fentanyl citrate (Actiq or Fentora) or nicotine (Nicorette gum) may be administered transmucosally. However, the greater penetrability accounts for the toxicity associated with improper application to a mucosal surface.^{5,23} A small amount of xenobiotic can enter the body by way of the skin appendages, such as the sweat glands or hair follicles.^{5,22} Furthermore, application of salicylic acid for treatment of hyperkeratinization disorders can cause salicylate poisoning.^{1,27}

Properties of the skin that account for pharmacokinetic variability include hydration status and temperature. Absorption varies based on the site of application on the body and is based on both thickness of the stratum corneum and blood flow.^{2,25,26} Although the average skin thickness of the human body is 40 microns, it ranges between 20 and 80 microns because of many factors, including body location, race, age, and sex. As an example, in skin samples from eight individuals, there was more than a 50% difference in the permeability of fentanyl.¹⁵ Because the stratum corneum thickness may be most relevant to diffusion rates, those areas that have similar thickness, such as the chest, extremities, and abdomen, provide the most consistent delivery and are generally used as sites for transdermal device application.^{26,28} Intertriginous areas, where skin contacts other skin (axillae, groin, inframammary, and intergluteal), may allow greater absorption because of enhanced contact surface, temperature, and moisture.

Active Administration

The passive approach requires the optimization of formulation or xenobiotic carrying vehicle to increase skin permeability. However, passive methods do not greatly improve the permeation of xenobiotics with MWs greater than 500 Da. In contrast active methods, normally involving physical or mechanical methods of enhancing delivery are generally superior. The delivery of xenobiotics of differing lipophilicity and MW, including proteins, peptides, vaccines, and oligonucleotides, is improved by active energy-requiring techniques such as iontophoresis, electroporation, and ultrasonography.^{10,21} In general, these techniques are not yet in wide use (Tables SC1–1 and SC1–2).

TABLE SC1–1. Common Xenobiotics Available in Patch Formulations

Buprenorphine (BuTrans)

Clonidine (Catapres-TTS, generic)

Estradiol (Climara)

Estradiol/levonorgestrel (Climara Pro)

Norelgestromin/ethinyl estradiol (Ortho Evra)

Fentanyl (Duragesic, Novaplus Fentanyl, generic)

Granisetron (Sancuso)

Methylphenidate (Daytrana)

Nicotine (Habitrol, Nicoderm CQ, Nicotrol, generic)

Nitroglycerin (Nitro-Dur)

Oxybutynin (Oxytrol)

Rivastigmine (Exelon)

Rotigotine (Neupro)

Scopolamine (Transderm Scop)

Selegiline (Emsam)

Testosterone (Androderm) and (Intrinsa)

TABLE SC1–2. Description of Advanced Transdermal Drug Delivery Systems

Electroporation: uses high-voltage microsecond duration electrical pulses to create transient pores within the skin (for larger molecules such as peptides)

Iontophoresis: uses electrodes to pass a small current through a xenobiotic (pilocarpine for sweat testing for cystic fibrosis and for lidocaine)

Ultrasonography: uses low-frequency ultrasound to promote transcutaneous delivery, also called sonophoresis

Microneedle-based devices: approximately 10 to 100 microns in length, generally arranged in arrays on patch devices; each microneedle is coated in xenobiotic to be delivered, and the small size avoids the production of pain

Needleless injection: compressed air is used to force xenobiotics across the skin surface; may deliver local anesthetics before intravenous line placement

Patch Technology

In most current patches, the xenobiotic to be delivered is incorporated into the adhesive layer. There may be multiple layers of adhesive separated by membranes that serve to regulate the release. To allow a longer duration of drug delivery, a reservoir may be added. This compartment contains the xenobiotic in solution or suspension, and a rate-regulating membrane ensures that the release follows zero order kinetics to avoid fluctuations in concentration. Increasing the surface area of contact by enlarging the patch proportionally increases the amount of xenobiotic delivered. The membrane itself is not altered. Removal of the rate-regulating membrane, however, results in rapid absorption of toxic quantities of xenobiotic.⁷

The initial fentanyl patch (Duragesic) used a reservoir that contained a large quantity of xenobiotic. This reservoir could have been accessed inadvertently by a child chewing the patch or intentionally by a person seeking to abuse the liquid contents.¹⁹ Cutting the reservoir patch could disperse the fentanyl and result in either overdose or loss of analgesia. Patch construction defects also occurred that potentially allowed leakage.¹³ Alternatively, by incorporating the xenobiotic into a fabric mesh, the matrix patch eliminates the reservoir and reduces the risk for abuse. The matrix patch may be cut to change dosage delivered, based on surface contact area, without risking spillage of any liquid content. The clinical pharmacology of the matrix fentanyl patch is similar to that of the reservoir patch.⁸

Pharmacokinetics

The initial detection of a xenobiotic in the serum after transdermal application is not surprisingly delayed compared with other routes of administration. The delay depends on the properties of the xenobiotic, the skin, and the environment. Very lipophilic xenobiotics form a depot in the subcutaneous tissue as they slowly dissolve in the aqueous tissue for diffusion to allow vascular uptake. Highly hydrophilic xenobiotics slowly penetrate the lipid layers of the epidermis, which is why ionic (salt) forms of xenobiotics are administered by a subcutaneous or intramuscular route. For example, fentanyl will not be detected in the serum before 1 to 2 hours after placement of a patch, and the peak concentration may not occur for one day or longer. For this reason, the use of a fentanyl patch is not indicated for the treatment of acute pain, particularly postoperative pain.¹⁹ Because the natural history of acute pain is to rapidly improve over several days, during which time the fentanyl concentrations continue to rise, the risk of toxicity rises.²⁹ However, in patients with chronic pain, this pharmacokinetic profile may be beneficial as long as opioids are indicated and safe use is monitored. Furthermore, as noted, permeation enhancers may alter the xenobiotic or the skin sufficiently to alter the absorption kinetics.

The pharmacokinetic profiles of serial doses of patches is based on removal of the patch after the specified time period and application of a new patch to a different location.¹⁹ This is important to allow a new subcutaneous depot to form while the existing depot is absorbed rather than adding a bolus dose from the adhesive to the existing depot.

Washing the skin or removing the patch will not result in a rapid fall in serum concentrations or a reduction in clinical effect.¹² Rather, these will resolve over several hours because of the persistence of the dermal depot.¹⁹ For example, the effective half-life of fentanyl after removal of a fentanyl patch is approximately 18 hours.¹² Therefore, simple removal of the fentanyl patch will not be sufficient treatment of a patient experiencing respiratory depression, and respiratory support or naloxone should be used.

Adverse Effects

Because transdermal administration places the xenobiotic in close contact with the environment, there is substantial risk of variation in absorption because of changes in ambient conditions. For example, patches exposed to heat, from heating blankets or saunas, can release xenobiotic at a rate greater than expected under conventional ambient conditions.⁴ Exposed patches may be damaged, either during the manufacturing process or subsequently, which can alter their release profile, resulting in toxicity.¹³ Certain patches, such as those with a metal backing, can get exceedingly hot during exposure to magnetic resonance imaging studies and result in burns.

Despite these techniques to enhance xenobiotic delivery, transdermal systems require that large amounts of xenobiotic be present externally to maximize the transcutaneous gradient. Much of the xenobiotic typically remains in the patch when it is removed after its intended course of therapy,¹⁷ raising concerns for safe disposal, especially around children,³⁰ and abuse potential among others.¹⁴ This latter issue is of greatest concern with the fentanyl reservoir patch.¹⁹

Perhaps the most insidious adverse effect associated with patches is their complicated pharmacology. Because many prescribers are unfamiliar with the dosing and initiation of therapy with transdermal products, those xenobiotics with consequential adverse effects in overdose, such as fentanyl, are commonly linked to poor outcomes even with intended therapeutic use.^{9,19}

SUMMARY

- Few xenobiotics have the appropriate chemical properties, such as lipophilicity and potency, to permit transdermal absorption.
- Transdermal delivery of a xenobiotic has certain therapeutic advantages over other routes, such as bypassing first-pass hepatic metabolism and providing a discreet administration.
- The pharmacokinetics of transdermal xenobiotic delivery are unique compared with other routes. Absorption is typically slower but more prolonged, which is potentially beneficial in situations in which long-term, continuous dosing is required.

19 FLUID, ELECTROLYTE, AND ACID–BASE PRINCIPLES

Alan N. Charney and Robert S. Hoffman

A meaningful analysis of fluid, electrolyte, and acid–base abnormalities must be based on the clinical characteristics of each patient. Although a rigorous appraisal of laboratory parameters often yields the correct differential diagnosis, the history and physical examination provide an understanding of the extracellular fluid volume (ECFV) and pathophysiology. Thus, the evaluation always begins with an overall assessment of the patient's status.

INITIAL PATIENT ASSESSMENT

History

The history should be directed toward clinical questions associated with fluid and electrolyte abnormalities. Xenobiotic exposure commonly results in fluid losses through the respiratory system (hyperpnea and tachypnea), gastrointestinal (GI) tract (vomiting and diarrhea), skin (diaphoresis), and kidneys (polyuria). Patients with ECFV depletion may complain of dizziness, thirst, and weakness. Usually the patients can identify the source of fluid loss.

A history of exposure to nonprescription and prescription medications, alternative or complementary therapies, and other xenobiotics may suggest the most likely electrolyte or acid–base abnormality. In addition, premorbid conditions and the ambient temperature and humidity should always be considered.

Physical Examination

The vital signs are invariably affected by significant alterations in ECFV. Whereas hypotension and tachycardia may characterize life-threatening ECFV depletion, an initial finding may be an increase of the heart rate and a narrowing of the pulse pressure. Abnormalities may be recognized through an ongoing dynamic evaluation, realizing that the measurement of a single set of supine vital signs offers useful information only when markedly abnormal. Orthostatic pulse and blood pressure measurements provide a more meaningful determination of functional ECFV status ([Chaps. 3 and 17](#)).

The respiratory rate and pattern can give clues to the patient's metabolic status. Hyperventilation (manifested by tachypnea, hyperpnea, or both) may be caused by a primary respiratory stimulus (respiratory alkalosis) or may be a response to the presence of metabolic acidosis. Although hypoventilation (bradypnea or hypopnea or both) is present in patients with metabolic alkalosis, it is rarely clinically significant except in the presence of chronic lung disease. More commonly, hypoventilation is associated with a primary depression of consciousness and respiration as well as respiratory acidosis. Unless the clinical scenario (ie, nature of the overdose or poisoning, presence of renal or pulmonary disease, findings on physical examination or laboratory testing) is diagnostic, arterial or venous blood gas analysis is required to determine the acid–base disorder associated with a change in ventilation.

The skin should be evaluated for turgor, moisture, and the presence or absence of edema. The moisture of the mucous membranes can also provide valuable information. These are nonspecific parameters and may not correlate directly with the status of hydration. This dissociation is especially true with xenobiotic exposure because many xenobiotics alter skin and mucous membrane moisture without necessarily altering ECFV status. For example, antimuscarinics commonly result in dry mucous membranes and skin without producing ECFV depletion. Conversely, patients exposed to sympathomimetics (eg, cocaine) or cholinergics (eg, organic phosphorus compounds) may have moist skin and mucous membranes even in the presence of significant fluid losses. This dissociation of ECFV and cutaneous characteristics reinforces the need to assess patients meticulously.

The physical findings associated with electrolyte abnormalities are generally nonspecific. Hyponatremia, hypernatremia, hypercalcemia, and hypermagnesemia all may produce a depressed level of consciousness. Neuromuscular excitability such as tremor and hyperreflexia may occur with hypocalcemia, hypomagnesemia, hyponatremia, and hyperkalemia. Weakness may be caused by either hyperkalemia or hypokalemia. Also, multiple, concurrent electrolyte disorders can produce confusing clinical presentations, or patients may appear normal. Rarer diagnostic findings, such as Chvostek and Trousseau signs (primarily found in hypocalcemia), may be useful in assessing patients with potential xenobiotic exposures.

Rapid Diagnostic Tools

The electrocardiogram (ECG) is a useful tool for screening several common electrolyte abnormalities (Chap. 16). It is easy to perform, rapid, inexpensive, and routinely available. Unfortunately, because poor sensitivity (0.43) and moderate specificity (0.86) were demonstrated when ECGs were used to diagnose hyperkalemia, in actuality, the test is of limited diagnostic value.¹⁴⁰ However, the ECG is valuable for the evaluation of changes in serum potassium and calcium concentrations ($[K^+]$ and $[Ca^{2+}]$) in an individual patient.

In many patients, bedside assessment of urine specific gravity by dipstick analysis may provide valuable information about ECFV status. A high urine specific gravity (>1.015) signifies concentrated urine and is often associated with ECFV depletion. However, urine specific gravity may be similarly elevated in conditions of ECFV excess, such as congestive heart failure or third spacing. Furthermore, when renal impairment or diuretic use is the source of the volume loss, the specific gravity is usually approximately 1.010 (known as isosthenuria). Patients with lithium-induced diabetes insipidus (DI) excrete dilute urine (specific gravity <1.010) despite ongoing water losses, and patients with excess antidiuretic hormone (ADH) secretion (eg, methylenedioxymethamphetamine {MDMA}) excrete concentrated urine (specific gravity >1.015) in the presence of a normal to expanded ECFV.

The urine dipstick is particularly useful for rapidly determining the presence of ketones, which are often associated with common causes of metabolic acidosis (eg, diabetic ketoacidosis, salicylate poisoning, alcoholic ketoacidosis). The urine ferric chloride test rapidly detects exposure to salicylates with a high sensitivity and specificity although it is rarely used today (Chap. 39).

Laboratory Studies

A simultaneous determination of the venous serum electrolytes, blood urea nitrogen (BUN), glucose, and arterial or venous blood gases is adequate to determine the nature of the most common acid–base, fluid, and electrolyte abnormalities. More complex clinical problems may require determinations of urine and serum osmolalities, urine electrolytes, serum ketones, serum lactate, and other tests. A systematic approach to common problems is discussed in the following sections.

ACID–BASE ABNORMALITIES

Definitions

The lack of a clear understanding and precise use of the terminology of acid–base disorders often leads to confusion and error. The following definitions provide the appropriate frame of reference for the remainder of the chapter and this textbook.

Whereas the terms acidosis and alkalosis refer to processes that tend to change pH in a given direction, acidemia and alkalemia only refer to the actual pH. By definition, a patient is said to have:

- A metabolic acidosis if the arterial pH is less than 7.40 and serum bicarbonate concentration ($[HCO_3^-]$) is less than 24 mEq/L. Because acidemia stimulates ventilation (respiratory compensation), metabolic acidosis is usually accompanied by a PCO_2 less than 40 mm Hg.
- A metabolic alkalosis if the arterial pH is greater than 7.40 and serum $[HCO_3^-]$ is greater than 24 mEq/L. Because alkalemia inhibits ventilation (respiratory compensation), metabolic alkalosis is usually accompanied by a PCO_2 greater than 40 mm Hg.
- A respiratory acidosis if the arterial pH is less than 7.40 and partial pressure of carbon dioxide (PCO_2) is greater than 40 mm Hg. Because an elevated PCO_2 stimulates renal acid excretion and the generation of HCO_3^- (renal compensation), respiratory acidosis is usually accompanied by a serum $[HCO_3^-]$ greater than 24 mEq/L.
- A respiratory alkalosis if the arterial pH is greater than 7.40 and PCO_2 is less than 40 mm Hg. Because a decreased PCO_2 decreases renal net acid excretion and increases the excretion of HCO_3^- (renal compensation), respiratory alkalosis is usually accompanied by a serum $[HCO_3^-]$ less than 24 mEq/L.

It is important to note that under most circumstances, a venous pH permits an approximation of arterial pH (see Chap. 29 for a further discussion of the relationship between arterial and venous pH). Any combination of acidoses and alkaloses can be present in any one patient at any given time. The terms acidemia and alkalemia refer only to the resultant arterial pH of blood (acidemia referring to a pH <7.40 and alkalemia referring to a pH >7.40). These terms do not describe the processes that led to the alteration in pH. Thus, a patient with acidemia must have a primary metabolic or respiratory acidosis but may have an alkalosis present at the same time. Clues to the presence of more than one acid–base abnormality include the clinical presentation, an apparent excess or insufficient “compensation” for the primary acid–base abnormality, a delta (Δ) anion gap-to- $\Delta [HCO_3^-]$ ratio that significantly deviates from one, or an electrolyte abnormality that is uncharacteristic of the primary acid–base disorder.

Determining the Primary Acid–Base Abnormality

It is helpful to begin by determining whether the patient has an acidosis or an alkalosis. This is followed by an assessment of the pH, PCO_2 , and $[\text{HCO}_3^-]$. With these three parameters defined, the patient's primary acid–base disorder can be classified using the aforementioned definitions. Next it is important to determine whether the compensation of the primary acid–base disorder is appropriate. It is generally assumed that overcompensation cannot occur.⁹⁷ That is, if the primary process is metabolic acidosis, respiratory compensation tends to raise the pH toward normal but never to greater than 7.40. If the primary process is respiratory alkalosis, compensatory renal excretion of HCO_3^- tends to lower the pH toward normal but not to less than 7.40. The same is true for primary metabolic alkalosis and primary respiratory acidosis. As a rule, compensation for a primary acid–base disorder that is inadequate or excessive is indicative of the presence of a second primary acid–base disorder.

Based on patient data, the Winters equation (Equation 19–1)⁷ predicts the degree of the respiratory compensation (the decrease in PCO_2) in metabolic acidosis as follows:

$$\text{PCO}_2 = (1.5 \times [\text{HCO}_3^-]) + 8 \pm 2 \quad (\text{Eq. 19–1})$$

Thus, in a patient with an arterial $[\text{HCO}_3^-]$ of 12 mEq/L, the predicted PCO_2 may be calculated as

$$(1.5 \times 12) + 8 \pm 2$$

or

$$26 \pm 2 \text{ mm Hg.}$$

If the actual PCO_2 is substantially lower than is predicted by the Winters equation, it can be concluded that both a primary metabolic acidosis and a primary respiratory alkalosis are present. If the PCO_2 is substantially higher than the predicted value, then both a primary metabolic acidosis and a primary respiratory acidosis are present.

An alternative to the Winters equation is the observation by Narins and Emmett that in compensated metabolic acidosis, the arterial PCO_2 is usually the same as the last two digits of the arterial pH.⁹⁷ For example, a pH of 7.26 predicts a PCO_2 of 26 mm Hg.

Guidelines are also available to predict the compensation for metabolic alkalosis,⁵⁶ respiratory acidosis, and respiratory alkalosis.⁷⁴ Patients with a metabolic alkalosis compensate by hypoventilating, resulting in an increase of their PCO_2 above 40 mm Hg. However, the concomitant development of hypoxemia limits this compensation so that respiratory compensation in the presence of a metabolic alkalosis usually results in a PCO_2 of 55 mm Hg or less. It is difficult to be more accurate about the expected respiratory compensation for a metabolic alkalosis, although the compensation, as in the case of metabolic acidosis, is nearly complete within hours of onset.

By contrast, the degree of compensation in primary respiratory disorders depends on the length of time the disorder has been present. In a matter of minutes, primary respiratory acidosis results in an increase in the serum $[\text{HCO}_3^-]$ of 0.1 times the increase (Δ) in the PCO_2 . This increase is a result of the production and dissociation of H_2CO_3 . Over a period of days, respiratory acidosis causes the compensatory renal excretion of acid. This compensation increases the serum $[\text{HCO}_3^-]$ by 0.3 times the ΔPCO_2 . Primary respiratory alkalosis acutely decreases the serum $[\text{HCO}_3^-]$ by 0.2 times the ΔPCO_2 . If a respiratory alkalosis persists for several days, renal compensation, by the urinary excretion of HCO_3^- , decreases the serum $[\text{HCO}_3^-]$ by 0.4 times the ΔPCO_2 .

Calculating the Anion Gap

The concept of the anion gap is said to have arisen from the “Gamblegram” originally described in 1939;⁴⁴ however, its use was not popularized until the determination of serum electrolytes became routinely available. The law of electroneutrality states that the net positive and negative charges of all fluids must be equal. Thus, all of the negative charges present in the serum must equal all of the positive charges, and the sum of the positive charges minus the sum of the negative charges must equal zero. The problem that immediately arose (and produced an “anion gap”) was that all charged species in the serum were not routinely measured.

Normally present but not routinely measured cations include calcium and magnesium; normally present but not routinely measured anions include phosphate, sulfate, albumin, and organic anions (eg, lactate and pyruvate).³⁶ Whereas Na^+ and K^+ normally account for 95% of extracellular cations, Cl^- and HCO_3^- account for 85% of extracellular anions. Thus, because more cations than anions are among the electrolytes usually measured, subtracting the anions from the cations normally yields a positive number, known as the anion gap. The anion gap is therefore derived as shown in Equation 19–2:

$$\begin{aligned}
& [\text{Na}^+] + [\text{K}^+] + [\text{Unmeasured Cations (U}_c\text{)}] = [\text{Cl}^-] + [\text{HCO}_3^-] \\
& \quad + [\text{Unmeasured Anions (U}_a\text{)}] \\
& \text{Anion Gap} = [\text{U}_a] - [\text{U}_c]
\end{aligned}$$

or

$$\text{Anion Gap} = ([\text{Na}^+] + [\text{K}^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-]) \quad (\text{Eq. 19-2})$$

Because the serum $[\text{K}^+]$ varies over a limited range of perhaps 1–2 mEq/L above and below normal and therefore rarely significantly alters the anion gap, it is often deleted from the equation for simplicity. Most prefer this approach, yielding Equation 19–3:

$$\text{Anion Gap} = ([\text{Na}^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-]) \quad (\text{Eq. 19-3})$$

Using Equation 19–3, the normal anion gap was initially determined to be 12 ± 4 mEq/L.³⁶ However, because the normal serum $[\text{Cl}^-]$ is higher on modern laboratory instrumentation, the current range for a normal anion gap is 7 ± 4 mEq/L.¹³⁸

A variety of pathologic conditions may result in a rise or fall of the anion gap. High anion gaps result from increased presence of unmeasured anions or decreased presence of unmeasured cations (Table 19–1).^{36,80} Conversely, a low anion gap results from an increase in unmeasured cations or a decrease in unmeasured anions (Table 19–2).^{36,42,52,119}

TABLE 19–1. Xenobiotic and Other Causes of a High Anion Gap

<i>Increase in Unmeasured Anions</i>	<i>Decrease in Unmeasured Cations</i>
Metabolic acidosis (Table 19–3)	Simultaneous hypomagnesemia, hypocalcemia, or hypokalemia
Therapy with sodium salts of unmeasured anions	
Sodium citrate	
Sodium lactate	
Sodium acetate	
Therapy with certain antibiotics	
Carbenicillin	
Sodium penicillin	
Alkalosis	

TABLE 19–2. Xenobiotic and Other Causes of a Low Anion Gap

<i>Increase in Unmeasured Cations</i>	<i>Decrease in Unmeasured Anions</i>	<i>Overestimation of Chloride</i>
Hypercalcemia	Hypoalbuminemia	Bromism
Hypermagnesemia	Dilution	Iodism
Hyperkalemia		Nitrate excess
Lithium poisoning		
Multiple myeloma		

Anion Gap Reliability

Several authors have considered the usefulness of the anion gap determination.^{19,43,64} When 57 hospitalized patients were studied to determine the cause of elevated anion gaps in patients whose anion gap was greater than 30 mEq/L, the cause was always a metabolic acidosis with elevated lactate or ketoacidosis.⁴³ In patients with smaller elevations of the anion gap, the ability to define the cause of the elevation diminished; in only 14% of patients with anion gaps of 17 to 19 mEq/L could the cause be determined. Another study determined that although the anion gap is often used as a screening test for hyperlactatemia (as a sign of poor perfusion), only patients with the highest serum lactate concentrations had elevated anion gaps.⁶⁴ Finally, in a sample of 571 patients, those with greater elevations in anion gaps tended to have more severe illness. This logically correlated with higher admission rates, a greater percentage of admissions to intensive care units, and a higher mortality rate.¹⁹ Thus, although the absence of an increased anion gap does not exclude significant illness, a very elevated anion gap can generally be attributed to a specific cause (typically lactate or ketones) and usually indicates a relatively severe illness.

Metabolic Acidosis

After the diagnosis of metabolic acidosis is established by finding an arterial pH less than 7.40, $[\text{HCO}_3^-] < 24 \text{ mEq/L}$, and $\text{PCO}_2 < 40 \text{ mm Hg}$, the serum anion gap should be analyzed. Indeed, the popularity of the anion gap is primarily based on its usefulness in categorizing metabolic acidosis as being of the high anion gap or normal anion gap type. This determination should be made after correcting the anion gap for the effect of hypoalbuminemia, a common and important confounding factor in sick patients. The anion gap decreases approximately 3 mEq/L per 1-g/dL decrease in the serum [albumin].⁴¹ In general, the electrolyte abnormalities that frequently accompany metabolic acidosis usually have only small and insignificant effects on the anion gap.

It should be noted that although many clinicians rely on the mnemonics **MUDPILES** (M, methanol; U, uremia; D, diabetic ketoacidosis; P, paraldehyde; I, iron; L, lactic acidosis; E, ethylene glycol; and S, salicylates) or **KULT** (K, ketones; U, uremia; L, lactate; T, toxins), to help remember this differential diagnosis, these mnemonics include rarely used drugs (phenformin, paraldehyde) and omit important others (eg, metformin, cyanide).

A high anion gap metabolic acidosis results from the absorption or generation of an acid that dissociates into an anion other than Cl^- that is neither excreted nor metabolized. The retention of this “unmeasured” anion (eg, glycolate in ethylene glycol poisoning) increases the anion gap. A normal anion gap metabolic acidosis results from the absorption or generation of an acid that dissociates into H^+ and Cl^- . In this case, the “measured” Cl^- is retained as HCO_3^- is titrated and its concentration reduced during the acidosis, and no increased anion gap is produced. Normal anion gap acidosis, also referred to as hyperchloremic metabolic acidosis, may be caused by intestinal or renal bicarbonate losses as in diarrhea or renal tubular acidosis, respectively. Other causes of high and normal anion gap metabolic acidoses are described elsewhere^{1,2} and shown in [Tables 19–3 and 19–4](#).

TABLE 19–3. Xenobiotic and Other Causes of a High Anion Gap Metabolic Acidosis

Carbon monoxide
Cyanide
Ethylene glycol
Hydrogen sulfide
Isoniazid
Iron
Ketoacidoses (diabetic, alcoholic, and starvation)
Lactate
Metformin
Methanol
Paraldehyde
Phenformin
Propylene glycol
Salicylates
Sulfur (inorganic)
Theophylline
Toluene
Uremia (acute or chronic kidney failure)

TABLE 19–4. Xenobiotic Causes of a Normal Anion Gap Metabolic Acidosis

Acetazolamide

Acidifying agents

Ammonium chloride

Arginine hydrochloride

Hydrochloric acid

Lysine hydrochloride

Calcineurin inhibitors (eg, tacrolimus, sirolimus)

Cholestyramine

Cleistanthus collinus (Plant)

Mafenide acetate (Sulfamylon)

Toluene

Topiramate

Narrowing the Differential Diagnosis of a High Anion Gap Metabolic Acidosis

The ability to diagnose the etiology of a high anion gap metabolic acidosis is an essential skill in clinical medicine. The following discussion provides a rapid and cost-effective approach to the problem. As always, the clinical history and physical examination may provide essential clues to the diagnosis. For example, iron poisoning is virtually always associated with significant GI symptoms, the absence of which essentially excludes the diagnosis ([Chap. 46](#)). Furthermore, when iron overdose is suspected, an abdominal radiograph may show the presence of tablets. The acidosis associated with isoniazid (INH) toxicity results from seizures, the absence of which excludes INH as the cause of a metabolic acidosis ([Chap. 58](#)). Methanol poisoning may be associated with visual complaints or abnormal funduscopic examination findings ([Chap. 109](#)). Methyl salicylate has a characteristic wintergreen odor ([Chap. 26](#)). When these findings are absent, the laboratory analysis must be relied on, as follows:

1. Begin with the serum electrolytes, BUN, creatinine, and glucose. A rapid blood glucose reagent test should be performed to help confirm or exclude hyperglycemia. Although hyperglycemia should raise the possibility of diabetic ketoacidosis, the absence of an elevated serum glucose does not exclude the possibility of euglycemic diabetic ketoacidosis,⁶⁶ or alcoholic or starvation ketoacidosis, which are often associated with normal or even low serum glucose concentrations. An elevated BUN and creatinine are essential to diagnose acute or chronic kidney failure.
2. Proceed to the urinalysis. Do not wait for the laboratory results because all of these urinary studies are easily performed. In addition, if there is a suspicion of a high anion gap metabolic acidosis and only the arterial or venous blood gas analysis is completed, the evaluation may begin here while the electrolyte determination is pending. A urine dipstick for glucose and ketones helps with the diagnosis of diabetic ketoacidosis and other ketoacidoses. However, the absence of urinary ketones does not exclude a diagnosis of alcoholic ketoacidosis ([Chap. 80](#)), and ketones are often present in severe salicylism ([Chap. 39](#)) and biguanide-associated metabolic acidosis ([Chap. 53](#)). The urine of a patient who has ingested fluorescein-containing antifreeze (ethylene glycol) may fluoresce when exposed to a Wood lamp. Also, because ethylene glycol is metabolized to oxalate, calcium oxalate crystals may be present in the urine of a poisoned patient. Although the presence of a fluorescent urine and calcium oxalate crystals are useful findings, their absence does not exclude ethylene glycol poisoning ([Chap. 109](#)). When clinically available, a urine ferric chloride test should be performed. Although highly sensitive and specific for the presence of salicylates, this test is not specific for the diagnosis of salicylism because small amounts of salicylate will be detected in the urine even days after its last use ([Chap. 39](#)). Thus, a serum salicylate concentration must be obtained to quantify the findings of a positive urine ferric chloride test result. A negative urine ferric chloride test result essentially excludes a diagnosis of salicylism.
3. A blood lactate concentration can be helpful. In theory, if the lactate (measured in mEq/L) can entirely account for the fall in serum $[\text{HCO}_3^-]$, then the cause of the high anion gap can be attributed to lactic acidosis. However, it is important to remember that glycolate (a metabolite of ethylene glycol) can produce a false-positive elevation of the lactate concentration with many current laboratory techniques.^{91,139}

When the above analysis of a high anion gap metabolic acidosis is nondiagnostic, the diagnosis is usually toxic alcohol ingestion, starvation, alcoholic ketoacidosis (with minimal urine ketones), or a multifactorial process involving small amounts of lactate and other anions. One approach is to provide the patient with 1 to 2 hours of intravenous (IV) hydration, dextrose, and thiamine. If the acidosis improves, the etiology is either ketoacidosis or metabolic acidosis with hyperlactatemia. In the absence of improvement, a more detailed search for the toxic alcohols, involving measurement of either the osmol gap or actual methanol and ethylene glycol concentrations, should be initiated (discussed later).

The Δ Anion Gap-to- $\Delta[\text{HCO}_3^-]$ Ratio

Many patients have mixed acid–base disorders such as metabolic acidosis and respiratory alkalosis. Depending on the relative effects of the acid–base disorders, the patient may have significant acidemia or alkalemia, minor alterations in pH, or even a normal pH. Although the clinical presentation, degree of compensation for the primary acid–base disorder, or the presence of unexpected electrolyte abnormalities may suggest whether more than one primary acid–base disorder is present, comparing the Δ anion gap (ΔAG) with the $\Delta[\text{HCO}_3^-]$ gap may be useful.

In a patient with a simple high anion gap metabolic acidosis, each 1 mEq/L decrease in the serum $[\text{HCO}_3^-]$ should (at least initially) be associated with a 1 mEq/L rise in the anion gap.⁹⁷ This occurs because the unmeasured anion is paired with the acid that is titrating the HCO_3^- . Any deviation from this direct relationship may be an indication of a mixed acid–base disorder.^{53,97,102} Thus, the ratio of the change in the anion gap (ΔAG) to the deviation of the serum $[\text{HCO}_3^-]$ from normal (Equation 19–4) evolved:

$$\text{Anion Gap Ratio} = \Delta\text{AG}/\Delta[\text{HCO}_3^-] \quad (\text{Eq. 19–4})$$

A ratio close to one would suggest a pure high anion gap metabolic acidosis. When the ratio is greater than one, there is a relative increase in $[\text{HCO}_3^-]$ that can result only from a concomitant metabolic alkalosis or renal compensation such as renal generation of HCO_3^- for a respiratory acidosis. Alternatively, when the ratio is less than one, the additional presence of either hyperchloremic (normal anion gap) metabolic acidosis or compensated respiratory alkalosis is suggested. Although the usefulness of this relationship has been supported strongly by some authors,^{100,102} others suggest that it is often flawed and frequently misleading.^{30,115}

After reviewing the arguments, the statements of one author³⁰ appear to be correct in concluding that “the exact relationship between the ΔAG and $\Delta[\text{HCO}_3^-]$ in a high anion gap metabolic acidosis is not readily predictable and deviation of the $\Delta\text{AG}/\Delta[\text{HCO}_3^-]$ ratio from unity does not necessarily imply the diagnosis of a second acid–base disorder.” Regardless, very large deviations from a value of one usually are associated with the presence of a second primary acid–base disorder.

The Osmol Gap

The osmol gap, which is sometimes used to screen for toxic alcohol ingestion, is defined as the difference between the values for the measured serum osmolality and the calculated serum osmolarity. Osmolarity is a measure of the total number of particles in 1 liter of solution. Osmolality differs from osmolarity in that the number of particles is expressed per kilogram of solution. Thus, osmolarity and osmolality represent molar and molal concentrations of solutes, respectively. In clinical medicine, whereas osmolarity is usually calculated, osmolality is usually measured.

Calculating osmolarity requires a summing of the known particles in solution. Because molarity and milliequivalents are particle-based measurements, unlike weight or concentration, the known constituents of serum have to be converted to molar values. Assumptions are required based on the extent of dissociation of polar compounds (eg, NaCl), the water content of serum, and the contributions of various other solutes such as Ca^{2+} and Mg^{2+} . The nature and limitations of these assumptions are beyond the scope of this chapter. Readers are referred to several reviews for more details.^{59,101} Many equations have been used and evaluated for calculating serum osmolarity. One investigation that used 13 different methods to evaluate sera from 715 hospitalized patients³² concluded that Equation 19–5 provided the most accurate calculation:

$$1.86([\text{Na}^+] \text{ in mEq/L}) + ([\text{Glucose}] \text{ in mg/dL}/18) + ([\text{BUN}] \text{ in mg/dL}/2.8) \quad (\text{Eq. 19–5})$$

Obvious sources of potential error in this calculation include laboratory error in determining the measured parameters and the failure to account for a number of osmotically active particles.

The measurement of serum osmolality has the potential for error stemming from the use of different laboratory

techniques.³⁵ It is essential to assure that the freezing point depression technique or osmometry is used because when the boiling point elevation method is used, xenobiotics with low boiling points (ethanol, isopropanol, methanol) will not be detected.

Conceptual errors may also result. In methanol poisoning, the methanol molecule has osmotic activity that is measured but not calculated, and no increase in the anion gap is present until it is metabolized to formate. Although the metabolite also has osmotic activity, its activity is accounted for by Na^+ in the osmolarity calculation because it is largely dissociated, existing as Na^+ formate. Thus, shortly after a ethylene glycol ingestion, there will be an elevated osmol gap and a normal anion gap; later, the anion gap will increase, and the osmol gap will decrease. This effect is highlighted by several case reports.^{9,26}

Using Equation 19–5 to calculate osmolarity, it is often stated that the “normal” osmol gap is 10 ± 6 mOsm/L.³² However, when more than 300 adult samples were studied with a more commonly used equation (Eq. 19–6),

$$2([\text{Na}^+] \text{ in mEq/L}) + ([\text{Glucose}] \text{ in mg/dL}/18) + ([\text{BUN}] \text{ in mg/dL}/2.8) \quad (\text{Eq. 19-6})$$

normal values were -2 ± 6 mOsm/L.⁵⁹ Almost identical results are reported in children.⁸⁷

The largest limitation of the osmol gap calculation is due to the documented large standard deviation around a small “normal” number.^{32,59} An error of 1 mEq/L ($<1.0\%$) in the determination of the serum $[\text{Na}^+]$ may result in an error of 2 mOsm/L in the calculation of the osmol gap. Considering this variability, the molecular weights (MWs) and relatively modest serum concentrations of the xenobiotics in question (eg, ethylene glycol; MW, 62 Da; at a concentration of 50 mg/dL theoretically contributes only 8.1 mOsm/L) and the predicted fall in the osmol gap as metabolism occurs, small or even negative osmol gaps can never be used to exclude toxic alcohol ingestion.⁵⁹ This overall concept is illustrated by an actual patient with an osmol gap of 7.2 mOsm (well within the normal range) who ultimately required hemodialysis for severe poisoning.¹²⁷ An additional error may result when including ethanol in the determination of the osmol gap. When present, ethanol is osmotically active and should be included in the calculated osmolarity. In theory, because the MW of ethanol is 46 g/mol, dividing the serum ethanol concentration (in mg/dL) by 4.6 will yield the osmolar contribution in mmol/L. However, because the physical interaction of ethanol with water is complex, it may be more scientifically accurate to divide by lower numbers as the ethanol concentration increases.¹⁰⁶ However, because the osmol gap is a screening tool, we suggest continuing to use the 4.6 divisor in an attempt to reduce clinical false-negative test results.

Finally, although exceedingly large serum osmol gaps may be suggestive of toxic alcohol ingestions, common conditions such as alcoholic ketoacidosis, metabolic acidosis with elevated lactate, kidney failure, and shock are all associated with elevated osmol gaps.^{65,118,123} This may be surprising because lactate, acetoacetate, and β -hydroxybutyrate should not account for any increase in the osmol gap because they are charged (and accounted for in the osmolarity calculation). Apparently, these conditions are associated with the accumulation of small uncharged molecules in the serum.

Thus, although the negative and positive predictive values of the osmol gap are too poor to recommend this test to routinely screen for xenobiotic ingestion, the presence of very high osmol gaps (>50 – 70 mOsm/L) usually indicates a diagnosis of toxic alcohol ingestion (Chap. 109).

Differential Diagnosis of a Normal Anion Gap Metabolic Acidosis

Although the differential diagnosis of a normal anion gap metabolic acidosis is extensive (Table 19–4), most cases result from either urinary or GI HCO_3^- losses: renal tubular acidosis (RTA) or diarrhea, respectively. A number of xenobiotics also can cause this disorder, including toluene,²³ which also may cause a high anion gap metabolic acidosis. When the findings of the history and physical examination cannot be used to narrow the differential diagnosis, the use of a urinary anion gap is suggested.^{13,110}

The urinary anion gap can be calculated as shown in Equation 19–7:

$$([\text{Na}^+] + [\text{K}^+]) - [\text{Cl}^-] \quad (\text{Eq. 19-7})$$

The size of this gap is inversely related to the urinary ammonium (NH_4^+) excretion.⁵¹ As NH_4^+ elimination increases, the urinary anion gap narrows and may become negative because NH_4^+ serves as an unmeasured urinary cation and is accompanied predominantly by Cl^- .

The normal anion gap metabolic acidosis associated with diarrhea results from HCO_3^- loss. During this process, the kidney’s ability to eliminate NH_4^+ is undisturbed; in fact, it increases as a normal response to the acidemia. Thus, with GI HCO_3^- losses the urinary anion gap should decrease and may become negative. By contrast, a patient with RTA has lost the

ability to either reabsorb HCO_3^- (type 2 RTA) or increase NH_4^+ excretion in response to metabolic acidosis (types 1 and 4 RTA) and the urinary anion gap should become more positive. Indeed, when the urinary anion gap was calculated in patients with diarrhea or RTA, it was found that patients with diarrhea had a mean negative gap (-20 ± 5.7 mEq/L) compared with a positive gap (23 ± 4.1 mEq/L) in those with RTA.⁵¹ Therefore, when evaluating the patient with a normal anion gap metabolic acidosis, the determination of a urinary anion gap may help to determine the source of the disorder.

Adverse Effects of Metabolic Acidosis

The acuity of onset and severity of metabolic acidosis determine the consequences of this disorder. Acute metabolic acidosis is usually characterized by obvious hyperventilation (caused by respiratory compensation). At arterial pH values less than 7.20, cardiac and central nervous system abnormalities may become evident. These may include decreases in blood pressure and cardiac output, cardiac dysrhythmias, and progressive obtundation.^{1,2} Chronic metabolic acidosis may not manifest clinical symptoms. The symptoms of anorexia and fatigue may be the only manifestations of chronic acidosis, and compensatory hyperventilation may be undetectable. Because the consequences of even severe metabolic acidosis are not specific, the presence of metabolic acidosis is most often suggested by the history and physical examination.

Management Principles in Patients with Metabolic Acidosis

The treatment of metabolic acidosis depends on its severity and cause. Most cases of severe poisoning, with a serum $[\text{HCO}_3^-]$ concentration less than 8 mEq/L and an arterial pH value less than 7.20 should probably be treated with HCO_3^- to increase the pH to greater than 7.20, as described in detail elsewhere.^{1,2} As an example, to raise the serum $[\text{HCO}_3^-]$ by 4 mEq/L in a 70-kg person with an estimated HCO_3^- distribution space of 50% of body weight, approximately 140 mEq must be administered. When ECFV overload (caused by heart failure, kidney failure, or the sodium bicarbonate therapy itself) cannot be prevented or managed by administering loop diuretics, hemofiltration or hemodialysis may be necessary.

In patients with arterial pH values greater than 7.20, the cause of the acidosis should guide therapy. Metabolic acidosis primarily caused by the overproduction of acid, as in the case of ketoacidosis and toxic alcohol poisoning, requires very large quantities of HCO_3^- and may not respond well to sodium bicarbonate therapy. Treatment in these patients should be directed at the cause of acidosis (eg, insulin and IV fluids in diabetic ketoacidosis; fomepizole in methanol, ethylene glycol and DEG poisonings {Antidotes in Depth: A30} fluids, glucose, and thiamine in alcoholic ketoacidosis; fluid resuscitation, antibiotics, and vasopressors in sepsis-induced hyperlactatemia). Patients with metabolic acidosis primarily caused by underexcretion of acid (eg, acute or chronic kidney failure, RTA) should be treated with a low-protein diet (if feasible) and oral sodium bicarbonate or substances that generate HCO_3^- during metabolism. Such patients can usually be managed with an oral sodium citrate solution such as Shohl solution, which yields 1 mEq base/mL. The goal of therapy is to increase the serum $[\text{HCO}_3^-]$ to 20 to 22 mEq/L and the pH to 7.30.

METABOLIC ALKALOSIS

Adverse Effects of Metabolic Alkalosis

Life-threatening metabolic alkalosis is rare but can result in tetany (from decreased ionized $[\text{Ca}^{2+}]$); weakness (from decreased serum $[\text{K}^+]$); or altered mental status leading to coma, seizures, and cardiac dysrhythmias. In addition, metabolic alkalosis shifts the oxyhemoglobin dissociation curve to the left, impairing tissue oxygenation (Chap. 29). The expected compensation for a metabolic alkalosis is hypoventilation and increased PCO_2 . As discussed before, respiratory compensation is irregular and inadequate at best, invoking the teleologic argument that hypoxia is more undesirable than alkalemia.⁹⁷ Several authors, however, have reported that severe hypoventilation and respiratory failure can occur in response to metabolic alkalosis, suggesting an actual, although uncommon, risk.¹⁰³

Approach to the Patient with Metabolic Alkalosis

Metabolic alkalosis results from GI or urinary loss of acid, administration of exogenous base, or renal HCO_3^- retention (ie, impaired renal HCO_3^- excretion). Table 19–5 lists the causes of metabolic alkalosis. Compared with metabolic acidosis, metabolic alkalosis is less common and less frequently a consequence of xenobiotic exposure.

TABLE 19–5. Xenobiotic and Other Causes of Metabolic Alkalosis

<i>Gastrointestinal Acid Loss</i>	<i>Urinary Acid Loss</i>	<i>Base Administration</i>	<i>Renal Bicarbonate Retention</i>
Nasogastric suction (protracted)	Common	Acetate (dialysis or hyperlimentation)	Hypercapnia (chronic)
Vomiting	Diuretics	Bicarbonate	Hypochloremia
	Glucocorticoids	Carbonate (antacids)	Hypokalemia
	Rare	Citrate	Volume contraction
	Hypercalcemia	(posttransfusion)	
	Licorice (containing glycyrrhizic acid)	Milk alkali syndrome	
	Magnesium deficiency		

The etiologies of metabolic alkalosis can be characterized from a therapeutic standpoint as chloride responsive or chloride resistant. Chloride-responsive etiologies such as diuretic use, vomiting, nasogastric suction, and Cl^- diarrhea are usually associated with a urinary $[\text{Cl}^-] < 10 \text{ mEq/L}$.⁵⁶ Patients with these disorders respond rapidly to infusion of 0.9% NaCl solution when concomitant therapy addresses the underlying problem.^{1,2} Chloride-resistant disorders exemplified by hyperaldosteronism and severe K^+ depletion are characterized by urinary $[\text{Cl}^-] > 10 \text{ mEq/L}$ and tend to be resistant to 0.9% NaCl solution therapy.^{46,56} Patients with these disorders often require K^+ repletion or drugs that reduce mineralocorticoid effects, such as spironolactone, before correction can occur.⁴⁶ When 0.9% NaCl solution repletion is ineffective or emergent correction of the alkalosis is required, some authors have suggested infusions of lysine or arginine HCl or dilute HCl.^{1,2} However, this technique is rarely necessary.

XENOBIOTIC-INDUCED AND OTHER ALTERATIONS OF WATER BALANCE

Significant fluid abnormalities commonly occur in the setting of xenobiotic exposure. GI losses in the form of vomiting, diarrhea, GI hemorrhage, and third spacing such as from GI burns result from a variety of xenobiotic toxicities and their management with emetics and cathartics. Renal fluid losses result from the ability of many xenobiotics to increase the glomerular filtration rate (inotropes), impair Na^+ reabsorption (diuretics), or enhance urine volume in response to an obligate solute load (salicylates). Fluid losses also may occur through the skin as a result of sweating (sympathomimetics, cholinergics, and uncouplers of oxidative phosphorylation) or the lung as a result of increased minute ventilation (salicylates and sympathomimetics) or bronchorrhea (cholinergics). To the extent that these lost fluids contain Na^+ , various signs, symptoms, and laboratory evidence of ECFV depletion may be present.

The diagnosis and treatment of abnormal serum electrolyte concentrations are usually addressed after repletion of the ECFV deficit with isotonic, Na^+ -containing fluids (eg, blood products, 0.9% NaCl solution, lactated Ringer solution). Other fluid balance issues are discussed in Chaps. 17 and 28 and in chapters relating to individual xenobiotics. This section focuses on body water balance (abnormalities of which manifest as hypernatremia and hyponatremia) and specifically on the toxicologically relevant syndromes of DI and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Sodium concentration in the extracellular space is intrinsically related to and directly reflects total body water balance. This occurs because the sodium cation is largely restricted to the extracellular space, and its serum concentration is primarily, if indirectly, controlled by factors that control water balance. Thus, both the serum $[\text{Na}^+]$ and plasma osmolality vary inversely with changes in the quantity of body water.

Plasma osmolality is maintained through a complex interaction between dietary water intake; the hypothalamus, pituitary gland, and kidney; and the effects of hormones such as arginine vasopressin (ADH) and adrenal mineralocorticoids.^{15,18,99,135} Briefly, changes in osmolality are caused by changes in water intake and insensible (dermal, respiratory, and stool) and sensible (urinary, sweat) water losses. Urinary water losses are controlled by ADH. Increases in the osmolality of the extracellular fluid (ECF) stimulate anterior hypothalamic osmoreceptors, thereby stimulating thirst and ADH synthesis and release by the posterior pituitary gland. ADH release reaches its maximum concentration at a plasma osmolality of about 295 mOsm/kg. ADH is transported to the kidney via the bloodstream, where it stimulates the synthesis of cyclic adenosine monophosphate (cAMP). cAMP increases the water permeability of the distal convoluted tubule and collecting duct by overstimulating the insertion of aquaporin channels in the apical membrane, increasing water reabsorption and urine concentration, and minimizing urinary water losses. Conversely, as plasma osmolality falls, thirst and ADH release are diminished. This results in decreased renal cAMP generation, decreased water permeability of the distal convoluted tubule and collecting duct, and excretion of a relatively dilute urine that ultimately corrects the body water excess. Marked alterations in water intake combined with perturbations of these various processes often lead to

hypernatremia or hyponatremia.

Hypernatremia

Table 19–6 summarizes the xenobiotics that cause hypernatremia. Hypernatremia may be caused by the parenteral administration of sodium-containing drugs or rapid and excessive oral Na⁺ intake.³ Oral NaCl and oral sodium citrate were once used as emetics and antiemetics, respectively. As might be expected, they produced severe hypernatremia.¹⁸ One case of fatal hypernatremia resulted from gargling with a supersaturated NaCl solution.⁹⁰ Similarly, massive ingestion of sodium hypochlorite bleach was associated with hypernatremia.¹¹³

TABLE 19–6. Xenobiotic Causes of Hypernatremia

<i>Sodium Gain</i>	<i>Water Loss</i>	<i>Water Loss Due to Diabetes Insipidus</i>
Antacids sodium bicarbonate	Cholestyramine	α-Adrenergic antagonists
Sodium salts (acetate, bicarbonate, chloride, citrate, hypochlorite)	Diuretics	Amphotericin
Seawater	Lactulose	Antivirals: abacavir, adefovir, cidofovir, tenofovir
	Mannitol	Colchicine
	Povidone-iodine	Demeclocycline
	Sorbitol	Ethanol
	Urea	Foscarnet
		Glufosinate
		Ifosfamide
		Lithium
		Lobenzarit disodium
		Methoxyflurane
		Mesalazine
		Minocycline
		Opioid antagonists
		Propoxyphene
		Rifampin
		Streptozotocin
		V ₂ -receptor antagonists: conivaptan, tolvaptan
		Valproic acid

More commonly, hypernatremia results from relatively electrolyte-free (hypotonic) water losses due to xenobiotics or conditions that cause urinary, GI, and dermal fluid losses.³ Indeed, all fluid losses from the body, except hemorrhage and those from fistulas, are hypotonic (and have the potential to cause hypernatremia). The lack of adequate fluid replacement is a key element in the development of hypernatremia because even the large fluid losses caused by DI or cholera-induced diarrhea will not cause hypernatremia if they are adequately replaced. Thus, in patients with hypernatremia caused by fluid losses, the reason why the losses were not replaced by the patient should always be sought.

Xenobiotics that produce significant diarrhea, such as lactulose, can cause hypernatremia through unreplaced stool water losses. A similar pathogenesis accounts for the hypernatremia caused by the polyethylene-containing solution used for bowel preparation for colonoscopy.¹² Of particular concern is the use of cathartics in the management of poisonings, especially when fluid losses are not anticipated. For example, multiple doses of sorbitol can produce severe hypernatremic dehydration and death in both children and adults.^{21,38,48,136}

Significant water loss also can occur through the skin. Although diffuse diaphoresis resulting from cocaine or organic phosphorus insecticide toxicity has the potential to produce hypernatremia, this rarely, if ever, occurs. However, application of a remedy containing hyperosmolar povidone–iodine to the skin of burned patients may produce significant water losses and hypernatremia.¹²⁰

Diagnosis and Treatment. The symptoms of significant hypernatremia consist largely of altered mental status ranging from confusion to coma and neuromuscular weakness that occasionally results in respiratory paralysis. If hypernatremia is associated with Na⁺ losses and marked ECFV depletion, cardiovascular symptoms, tachycardia, and orthostatic

hypotension may be present. Treatment consists of first replacing the Na^+ deficit (with isotonic fluids such as 0.9% NaCl solution), if present, and then replacing the water deficit. The water deficit may be estimated by assuming that the fractional increase in serum $[\text{Na}^+]$ is equal to the fractional decrease in total body water. Thus, a serum $[\text{Na}^+]$ that has increased by 10% (from 144 mEq/L–158 mEq/L) indicates that the water deficit is 10% (3.6 L in a 60-kg person with 36 L of body water).

When the hypernatremia develops over several hours, for example, as occurs after ingestion or administration of a sodium salt, rapid correction is indicated. However, when hypernatremia develops over several days or when the duration is unknown, slow correction of hypernatremia (over several days) is recommended.³ The adaptation of brain cells to the water deficit (including the gain of intracellular solute including K^+ , Na^+ , inositol, glutamate, taurine, and creatine) makes cerebral edema a frequent complication of rapid water replacement. Although some sources suggest that 0.9% NaCl solution is an appropriate replacement fluid regardless of the magnitude of the water deficit, more recent emphasis has been on the use of hypotonic fluids to correct hypernatremia in the absence of a significant sodium deficit.³

Diabetes Insipidus

The greatest water losses and therefore the potentially most severe cases of hypernatremia occur during DI, which is always characterized by greater or lesser degrees of hypotonic polyuria. DI may be neurogenic, resulting from failure to sense a rising osmolality or from a failure to release ADH, or nephrogenic, resulting from failure of the kidney to respond appropriately to ADH. Although there are many nontoxicologic causes of DI (eg, trauma, tumor, sarcoidosis, vascular, and congenital), xenobiotic-induced DI is also common and may be mediated through either central or peripheral mechanisms.

Ethanol, opioid antagonists, and α -adrenergic agonists all suppress ADH release.^{94,95} Lithium,^{79,122} demeclocycline,¹²¹ methoxyflurane,⁸³ propoxyphene, foscarnet,⁹⁸ mesalazine,⁸¹ streptozotocin, amphotericin,⁶¹ glufosinate,¹³⁰ lobenzarit,¹¹⁴ rifampin,¹⁰⁷ and colchicine¹³⁵ are associated with nephrogenic DI (Table 19–6). In addition, nephrogenic DI may be caused by severe hypokalemia from diuretic use and hypercalcemia from vitamin D poisoning.¹³⁵ Of all of these xenobiotics, lithium has been the most extensively evaluated. Although polyuria is a common finding with lithium therapy (occurring in 20%–70% of patients on maintenance therapy), the exact incidence of DI and hypernatremia is unknown. Estimates range from 10% to 20% to as high as 80%.

Diagnosis. Patients with DI complain of polyuria and polydipsia. Urine volumes typically exceed 30 mL/kg/d¹³⁵ and may be as high as 9 L/d with nephrogenic DI⁷⁹ and 12 to 14 L/d with neurogenic (central) DI.⁹⁵ Nocturia, fatigue, and decreased work performance are often noted.¹³⁵ Neurogenic DI resulting from hypothalamic or pituitary damage is typically associated with other signs of neuroendocrine dysfunction.⁹⁵

After polyuria is confirmed (eg, in adults, by measuring a urine output >200 mL over one hour), the urine osmolality or specific gravity should be measured. The diagnosis of DI is established by the occurrence of dilute urine (urine osmolality <300 mOsm/kg, urine specific gravity <1.010) in the presence of increased serum $[\text{Na}^+]$ and a serum osmolality greater than 295 mOsm/kg.¹³⁵ After this determination, a trial of desmopressin, an arginine vasopressin analog, helps to differentiate between neurogenic and nephrogenic DI. If the etiology of the DI is neurogenic, the patient will promptly respond to desmopressin with a decrease in urine output and increase in urine osmolality. In nephrogenic DI, desmopressin will have no significant effect.

Treatment. The initial approach to a hypernatremic patient with DI involves the repletion of the water deficit (as described earlier) and the restoration of electrolyte depletion, if necessary. If a reversible cause for the DI can be established, it should be corrected. Specifically, xenobiotics implicated as the cause of DI should be discontinued or their dose reduced. Patients with neurogenic DI should be maintained on either vasopressin or desmopressin. The latter is preferred because of the lack of vasopressor effects and ease of administration. In the past, patients were occasionally treated with oral medications known to produce SIADH (see later). Patients with nephrogenic DI can be treated with thiazide diuretics,³³ prostaglandin inhibitors,^{29,77} or amiloride, all of which reduce the urine flow rate.¹⁴

Hyponatremia

Hyponatremia may be associated with a high, normal, or low serum osmolality. Patients with myeloma or severe hyperlipidemia may exhibit artifactual hyponatremia whenever the measurement technique requires dilution of the serum sample rather than direct measurement by a sodium electrode. These patients have a normal serum osmolality and no symptoms related to their artifactual hyponatremia, and they require no therapy.

Hyperglycemic patients develop hyponatremia because the increase in plasma osmolality caused by hyperglycemia results in a water shift from the intracellular to the extracellular space. The reduction in serum $[\text{Na}^+]$, which may cause symptoms, is approximately 1.6 mEq/L for every 100 mg/dL increase in serum glucose concentration above normal. The contribution of hyperglycemia to the hyponatremia should be calculated to determine if other causes of hyponatremia should also be sought. All other causes of hyponatremia are associated with a low plasma osmolality. In fact, in the absence of

myeloma, hyperlipidemia, and hyperglycemia, the serum osmolality need not be measured in hyponatremic patients and may be assumed to be low.

Hyponatremia associated with a low plasma osmolality usually results from water intake in excess of the renal capacity to excrete it. When renal water excretion is normal, very large intake is required to cause hyponatremia. Usually such large quantities of water are ingested over a short period of time by people with psychiatric or neurologic disorders such as psychogenic polydipsia.^{50,111} Xenobiotic-induced water excess comparable to psychogenic polydipsia is quite uncommon. An example occurs during urologic procedures, such as transurethral resection of the prostate (TURP), in which large volumes of irrigation solution are required. Because the wounds are electrically cauterized, these fluids cannot contain conductive electrolytes such as sodium. Sorbitol, dextrose, and mannitol were tried as irrigation solutions in an attempt to maintain a normal osmolality, but their optical characteristics were undesirable during the surgery. Thus, irrigation during TURP is performed with glycine-containing solutions. If a large volume of 1.5% glycine (osmolality, 220 mOsm/kg) is absorbed through the prostatic venous plexus, a rapid reduction in serum $[Na^+]$ may result and will persist until the glycine is metabolized.^{58,89} Symptoms in these patients are probably a result of several factors: hyponatremia, the glycine itself, and NH_3 , a glycine metabolite. A similar complication has also been described during hysteroscopy.¹⁰⁴

Rarely, hyponatremia results from the loss of a body fluid with a $[Na^+]$ greater than the ECF $[Na^+]$ (of 154 mEq/L). This may occur in patients with adrenal insufficiency through hypertonic urinary losses (although increased ADH secretion as a consequence of ECF sodium depletion is probably a more important mechanism; see later discussion). In burn patients, Na^+ may be lost directly from the ECF. When treated with topical applications of silver nitrate cream, hyponatremia may develop from the diffusion of sodium through permeable skin into the hypotonic dressing.²⁴ Ingestion of licorice that contains glycyrrhizic acid produces a syndrome of hyponatremia, hypokalemia, and hypertension that resembles mineralocorticoid excess. Although the exact mechanism of hyponatremia is debated, one report suggested that a glycyrrhizic acid–induced reduction in 11- β -hydroxysteroid dehydrogenase activity could account for the findings.³⁷ Lithium, which is usually associated with DI and hypernatremia, has been reported to cause renal sodium wasting and hyponatremia that seems to be unrelated to ADH effects.⁸⁸

Most cases of hyponatremia are caused by water intake in excess of a reduced renal excretory capacity. This reduction in urinary water excretion may be physiologic (as during ECF sodium depletion) or pathologic (in association with kidney, heart, or liver failure).⁴ Because these conditions are accompanied by alterations in renal sodium handling, signs and symptoms of ECFV depletion, such as postural hypotension, or ECFV excess, such as edema, usually accompany the hyponatremia. Other patients cannot excrete water normally because malignancy or various brain or pulmonary diseases cause ADH secretion.⁴ In some cases, the tumors are associated with paraneoplastic disease and directly secrete ADH. Xenobiotics, such as diuretics, may cause ECFV depletion, but most directly stimulate ADH secretion or augment the renal effects of ADH. Drugs such as the thiazide diuretics cause hyponatremia by several mechanisms, including interference with maximal urinary dilution, and by ADH-induced water retention in response to decreased ECFV.^{4,40} Patients with excess secretion or action of ADH who have near-normal ECFV have SIADH. Table 19–7 summarizes these and other causes of hyponatremia.

TABLE 19–7. Xenobiotic and Other Causes of Hyponatremia

Angiotensin-converting enzyme inhibitors
Arginine
Diuretics
Glycine (transurethral prostatectomy syndrome)
Licorice (containing glycyrrhizic acid)
Lithium
Nonsteroidal antiinflammatory drugs
Primary polydipsia
SIADH
Silver nitrate
Amiloride

Amiodarone
Amitriptyline (and other cyclic antidepressants)
Antipsychotics
Atomoxetine
Biguanides (metformin and phenformin)
Bortezomib
Carbamazepine (and oxcarbamazepine)
Cisplatin (and other platinum chemotherapeutics)
Clofibrate
Cyclophosphamide
Desmopressin (DDAVP)
Diazoxide
Duloxetine
Hallucinogenic amphetamines, MDMA (methylenedioxymethamphetamine),
methylenedioxymethamphetamine,
methylenedioxymethamphetamine
ethcathinone
Nicotine
Opioids
Oxytocin
Selective serotonin reuptake inhibitors
Sibutramine
Sulfonylureas
Tramadol
Tranylcypromine
Valproate
Vasopressin
Vincristine and vinblastine

SIADH

SIADH is characterized by hyponatremia and plasma hypotonicity in the absence of abnormalities of ECFV, adrenal, thyroid, or kidney. Early reviews claimed that SIADH was a disorder of volume overload based largely on evidence of weight gain.⁹⁴ The consistent absence of edema, however, and the fact that the decrease in serum $[\text{Na}^+]$ cannot be accounted for by the fluid gain (weight gain) suggest that water retention is only part of the mechanism.⁷³ Urinary Na^+ loss and Na^+ redistribution from the extracellular to the intracellular space is apparently important as well.

There are many nontoxicologic etiologies of SIADH, most of which result from pulmonary or intracranial pathology. These causes include infections, malignancies, and surgery.^{4,73,95} Table 19–7 summarizes xenobiotics known to produce

SIADH. The antidiabetics, including drugs from both the sulfonylurea (eg, chlorpropamide) and biguanide (eg, metformin) classes, produce hyponatremia more commonly than other drugs.⁹³ Their actions are multifactorial and can include both the potentiation of endogenous ADH and the stimulation of ADH release.⁹³ Many psychiatric medications, including the selective serotonin reuptake inhibitors, cyclic antidepressants, and antipsychotics, are implicated in causing SIADH.^{71,78,126,133} The effects of these drugs may be mediated by the complex interactions between the dopaminergic and noradrenergic systems that control ADH release.¹²⁶ Additional evidence supports a role of serotonin in drug-induced SIADH. Serotonin (specifically 5-HT₂ or 5-HT_{1C} agonism) directly stimulates ADH release¹⁰ and water intake.⁶³ An important role of serotonin is supported by the occurrence of SIADH with MDMA use.⁶²

Diagnosis. The clinical presentation of patients with hyponatremia depends on the cause, the absolute serum [Na⁺], and the rate of decline in serum [Na⁺]. Patients with associated ECFV excess or depletion present with evidence of altered ECFV, as well as signs and symptoms of the disease that caused the abnormality in ECFV, such as adrenal insufficiency or heart failure.⁴ Rarely do these patients exhibit symptoms of hyponatremia and hyposmolality of body fluids per se. This may be because of the moderate degree of hyponatremia (>130 mEq/L) or the moderate rate of decline in [Na⁺] or because the loss of Na⁺ and water limits the development of cerebral edema.⁷⁶ It is important to note that patients with hyponatremia and a low plasma osmolality (excluding those with primary polydipsia) all have a urinary osmolality that is relatively high regardless of whether they have excess, diminished, or normal ECFV. Consequently, these disorders can only be differentiated by the history, physical examination, and other laboratory test results.

Patients with SIADH, if symptomatic, usually present with signs and symptoms of hyponatremia. As noted earlier, the clinical manifestations of hyponatremia are dependent on both the absolute serum [Na⁺] and its rate of decline.^{76,95} Whereas chronic, slow depression of the [Na⁺] is usually well tolerated, rapid decreases may be associated with symptoms and sometimes catastrophic events. Symptoms include headache, nausea, vomiting, restlessness, disorientation, depression, apathy, irritability, lethargy, weakness, and muscle cramps. In more severe cases, respiratory depression, coma, and seizures may develop.

The diagnosis of SIADH is based on establishing the presence of hyponatremia, a low serum osmolality, and impaired urinary dilution in the absence of edema, hypotension, hypovolemia, and kidney, adrenal, or thyroid dysfunction.⁷³ As discussed earlier, the presence of any of these clinical findings suggests that another cause of hyponatremia may be present. A serum uric acid concentration may be helpful in differentiating SIADH from other causes of hyponatremia. In the presence of hyponatremia and impaired urinary dilution, patients with SIADH have hypouricemia, but patients exhibiting ECFV excess or depletion characteristically have hyperuricemia.²⁷

Treatment. Treatment of patients with demonstrable ECFV excess or depletion should be directed at the abnormal ECFV and its cause rather than the hyponatremia. In almost all cases, the hyponatremia will improve with correction of the ECFV.^{4,76} In a similar way, correction of the serum glucose in hyperglycemic patients and the removal of glycine by hemodialysis in patients with the TURP syndrome will correct the serum [Na⁺]. The rate of correction of the serum [Na⁺] in these patients is generally not of concern.

In patients with SIADH, treatment begins with fluid restriction. Because the goal of this therapy is to establish a negative fluid balance, careful attention to intake and output is required. If an offending xenobiotic can be identified, it should be discontinued. Although most cases resolve in 1 to 2 weeks,^{73,95} SIADH caused by chronic cerebral or pulmonary conditions or by malignancy often persists. If this occurs, therapy with demeclocycline, lithium, or tolvaptan may be helpful because severe fluid restriction is often intolerable. Tolvaptan, an oral ADH antagonist with specificity for the V₂ receptor, is currently the recommended treatment for chronically hyponatremic patients in whom fluid restriction is unsuccessful because it is easier to titrate with fewer potential side effects than demeclocycline and lithium. In all asymptomatic or mildly symptomatic patients (usually patients with chronic hyponatremia of more than 2 days' duration), correction should proceed slowly and certainly at a rate less than 0.5 mEq/L/h during the first 48 hours. This is because if the correction of hyponatremia is faster than the reuptake of the solutes (K⁺, Na⁺, inositol, glutamate, taurine, and creatine) extruded from brain cells during the development of hyponatremia, brain shrinkage will occur with breaching of the blood–brain barrier. This effect may cause osmotic demyelination syndrome (ODS). ODS, which is associated with central pontine and extrapontine myelinolysis, may have a delayed onset of 2 to 6 days and causes irreversible brain damage and death in 50% and 15% of patients, respectively.^{4,11,128} Risk factors for ODS, in addition to too rapid correction of chronic hyponatremia, include serum [Na⁺] below 115 mEq/L and patients who are elderly, hypokalemic, alcoholic, or malnourished. In asymptomatic patients, as described earlier, water restriction is recommended and usually sufficient, but occasionally tolvaptan may be appropriate. When hyponatremia is associated with life-threatening clinical presentations, including respiratory depression, altered mental status, seizures, or coma, careful infusion of hypertonic 3% saline ([Na⁺] = 513 mEq/L) (eg, 1–2 mL/kg/h), with or without furosemide, is indicated.^{4,73} Alternatively, conivaptan (an ADH V₁ and V₂ receptor antagonist) may be administered intravenously as an initial bolus of 20 mg followed by a continuous infusion of 40 mg/d for no more than 4 days.^{55,57} In these symptomatic patients, the goal is to increase the serum [Na⁺] 1 mEq/L/h (5–6

mEq/L over 6 hours) or until the symptoms abate.^{4,76} After this initial correction and amelioration of symptoms, the serum [Na⁺] should be increased at a rate less than 0.5 mEq/L/h, preferably by water restriction alone. Formulas are available to help calculate the rate of correction of hyponatremia.⁴ Equation 19–8 may be helpful.

When 1 L of fluid is infused:

$$\text{Change in serum [Na}^+ \text{]} = \frac{\text{infusate [Na}^+ \text{]} - \text{serum [Na}^+ \text{]}}{\text{Total body water} + 1 \text{ L}} \quad (\text{Eq. 19-8})$$

where the infusate [Na⁺] in mEq/L equals:

3% Sodium chloride	513
0.9% Sodium chloride	154
Lactated Ringer solution	130
0.45% Sodium chloride	77
0.33% Sodium chloride	56

XENOBIOTIC-INDUCED ELECTROLYTE ABNORMALITIES

Potassium

Xenobiotic-induced alterations in serum [K⁺] are potentially more serious than alterations in other electrolyte concentrations because of the critical role of potassium in a variety of homeostatic processes. Potassium balance is complex.^{20,105,117} The total-body potassium content of an average adult is about 54 mEq/kg, of which only 2% is located in the intravascular space. The large intracellular store of potassium is maintained by a variety of systems, the most important of which is membrane Na⁺-K⁺-adenosine triphosphatase (ATPase). The relationship between total body stores and serum [K⁺] is not linear, and small changes in the total body potassium may result in dramatic alterations in serum concentrations, and, more important, in the ratio of extracellular to intracellular [K⁺].

People eating a western diet ingest 50 to 150 mEq/d of potassium, approximately 90% of which is subsequently eliminated in the urine. The body has two major defenses against a potassium load: acutely, potassium is transferred into cells; chronically, potassium is excreted in the urine by decreased proximal tubular reabsorption and increased distal tubular secretion (to a maximum of 600–700 mEq/d).²⁰ After a meal, K⁺ transfers into intracellular space through insulin and catecholamine-mediated uptake of potassium in liver and muscle cells.¹¹² Renal potassium excretion is primarily modulated by the renin–angiotensin–aldosterone system. In addition, the GI absorption of potassium decreases as the serum [K⁺] increases.

Hypokalemia results from decreased oral intake, GI losses caused by repeated vomiting or diarrhea, urinary losses through increased K⁺ secretion or decreased reabsorption, and processes that shift potassium into the intracellular compartment.^{18,20,137} Table 19–8 summarizes the xenobiotics commonly associated with hypokalemia.

TABLE 19–8. Xenobiotic Causes of Altered Serum Potassium

<i>Hypokalemia</i>	<i>Hyperkalemia</i>
β-Adrenergic agonists	α-Adrenergic agonists (phenylephrine)
Aminoglycosides	β-Adrenergic antagonists
Amphotericin	Amiloride
Barium (soluble salts)	Angiotensin-converting enzyme inhibitors
Bicarbonate	Angiotensin receptor blockers
Caffeine	Arginine hydrochloride
Carbonic anhydrase inhibitors	Cardioactive steroids
Cathartics	Fluoride
Chloroquine	Heparin
Cisplatin	Nonsteroidal antiinflammatory drugs
Dextrose	Penicillin (potassium)
Hydroxychloroquine	Potassium salts
Infliximab	Spironolactone
Insulin	Succinylcholine
Licorice (containing glycyrrhizic acid)	Triamterene
Loop diuretics	Trimethoprim
Metabolic alkalosis	
Osmotic diuretics	
Quinine	
Salicylates	
Sodium penicillin and its analogs	
Sodium polystyrene sulfate	
Sulfonylureas	
Sympathomimetics	
Tenofovir	
Theophylline	
Thiazide diuretics	
Toluene	

The neuromuscular manifestations of hypokalemia are reviewed elsewhere.⁷² Patients with hypokalemia are often asymptomatic when the decrease in serum $[K^+]$ is mild (serum concentrations of 3.0–3.5 mEq/L). Occasionally, hypokalemia interferes with renal concentrating mechanisms, and polyuria is noted. More significant potassium deficits (serum concentrations of 2.0–3.0 mEq/L) cause generalized malaise and weakness. As the $[K^+]$ falls to less than 2 mEq/L, weakness becomes prominent, and areflexic paralysis and respiratory failure may occur, often necessitating intubation and mechanical ventilation.⁷² Rhabdomyolysis is also likely. These neuromuscular manifestations are so prominent that they may be erroneously attributed to a neuromuscular syndrome such as Guillain-Barré. Other clinical findings associated with hypokalemia include GI hypoperistalsis (ileus); manifestations of cardioactive steroid toxicity; worsening hyperglycemia in patients with diabetes; and the symptoms and signs of the metabolic abnormalities that often accompany hypokalemia such as hyponatremia, metabolic acidosis, or alkalosis.¹³⁷

Electrocardiographic changes also are common, even with mild potassium depletion, although the absence of ECG changes should never be used to exclude significant hypokalemia. Common ECG findings of hypokalemia include depression of the ST segment, decreased T-wave amplitude, and increased U-wave amplitude ([Chap. 16](#)). These findings may herald life-threatening rhythm disturbances.¹³⁷

Treatment of hypokalemia involves discontinuing or removing the offending xenobiotic and correcting the potassium deficit. Potassium supplementation may be given orally or intravenously. The choice of potassium salt should be based on the associated acid–base abnormality, if present. Thus, potassium chloride should be administered when metabolic alkalosis is present, and another salt of potassium (eg, potassium citrate or potassium bicarbonate) should be administered when metabolic acidosis is present.¹³⁷ Potassium phosphate should be considered part of the K^+ supplement when hypophosphatemia is present, as occurs in diabetic ketoacidosis, or when hyperchloremia is present. Hypomagnesemia, which may cause or accompany hypokalemia (eg, in diuretic-induced hypokalemia), must be corrected because this abnormality may prevent successful potassium replacement.

The debate over the maximum safe infusion rate for IV potassium is summarized elsewhere.^{75,137} Based on experience with more than 1300 infusions, one group concluded that under intensive care monitoring, IV administrations of 20 mEq/h (by central or peripheral vein) were well tolerated. They also found that each 20 mEq of potassium administered resulted in an average increase in serum $[K^+]$ of 0.25 mEq/L. Others have used significantly larger doses (up to 100 mEq/h) in life-threatening circumstances.²⁸

Hyperkalemia results from decreased urinary elimination (renal insufficiency, potassium-sparing diuretics, hypoaldosteronism), increased intake (either orally or intravenously), or redistribution from tissue stores.^{18,20} The last mechanism is of major toxicologic importance. Overdoses of both cardioactive steroids (Chap. 65) and β -adrenergic antagonists (Chap. 62) cause hyperkalemia by promoting net potassium release from intracellular reservoirs. Presumably because of other protective mechanisms, overdose with a β -adrenergic antagonist produces only a moderate rise in serum $[K^+]$ (usually to 5.0–5.5 mEq/L). By contrast, a similar rise in serum $[K^+]$ as a consequence of blockade of the Na^+-K^+ -ATPase pump during acute cardioactive steroid toxicity may be lethal (Chap. 65). This suggests that hyperkalemia per se is not the cause of the lethality of cardioactive steroid toxicity. Thus, the focus of therapy should involve efforts to neutralize or eliminate the cardioactive steroid rather than reduce the serum $[K^+]$.¹⁶ Table 19–8 lists xenobiotics that cause hyperkalemia.

After oral overdoses of potassium salts, patients usually complain of nausea and vomiting. Ileus, intestinal irritation, bleeding, and perforation may complicate the clinical course.^{116,117} In the absence of potassium ingestion, GI symptoms of hyperkalemia are usually very mild. Neuromuscular manifestations include weakness with an ascending flaccid paralysis and respiratory compromise, with intact sensation and cognition.^{72,85,105} The similarity of these signs and symptoms to those associated with hypokalemia is striking, suggesting that hyperkalemia may be diagnosed with certainty only by laboratory measurement.

The cardiac manifestations of hyperkalemia are distinct, prominent, and life threatening. ECG patterns progress through characteristic changes.¹¹⁶ Although the progression of ECG changes is very reproducible, there is great individual variation with respect to the serum $[K^+]$ at which these ECG findings occur. Initially, the only ECG finding may be the presence of tall, peaked T waves. As the serum $[K^+]$ concentration increases, the QRS complex tends to blend into the T waves, the P-wave amplitude decreases, and the PR interval becomes prolonged. Next, the P wave is lost, and ST-segment depression occurs. Finally, the distinction between the S and T waves becomes blurred, and the ECG takes on a sine wave configuration (Chap. 16). Hemodynamic instability and cardiac arrest can result. As the patient's serum $[K^+]$ falls with therapy, these ECG changes resolve in a reverse fashion.

The treatment of severe hyperkalemia focuses on methods to (1) reverse the ECG effects, (2) transfer K^+ to the intracellular space, and (3) enhance K^+ elimination. Pharmacologic interventions, extensively discussed elsewhere,¹¹⁷ are summarized here. Calcium salt (eg, 10–20 mEq administered intravenously) (Antidote in Depth: A29) works almost immediately to protect the myocardium against the effects of hyperkalemia, although it does not reduce the serum $[K^+]$. However, a potentially life-threatening interaction occurs when the patient with cardioactive steroid toxicity is given calcium salts (Chap. 65); thus, this therapeutic modality is relatively contraindicated in such circumstances.

The administration of insulin (and dextrose to prevent hypoglycemia unless hyperglycemia is present), sodium bicarbonate, or inhalation of a β -adrenergic agonist all stimulate potassium entry into cells.⁸ They reduce the serum $[K^+]$ over approximately 30 minutes, but potassium begins to reenter the extracellular space over the next several hours. Cationic exchange resins, such as Na^+ polystyrene sulfonate, take longer to reduce the serum $[K^+]$ as they enhance GI potassium loss. Hemodialysis or peritoneal dialysis may be useful, especially when significant renal impairment is present.

Calcium

Calcium is the most abundant mineral in the body, and 98% to 99% is located in bone. Approximately half of the remaining 1% to 2% of calcium in the body is bound to plasma proteins (mostly albumin), and most of the rest is complexed to various anions, with free, ionized calcium representing a very small fraction of extraosseous stores. The serum $[Ca^{2+}]$ is maintained through interactions between dietary intake and renal elimination, modulated by vitamin D activity, parathyroid hormone, and calcitonin. More extensive discussions of calcium physiology are found elsewhere.^{6,96}

Xenobiotic-induced hypercalcemia is uncommon and usually caused by an increased dietary calcium as a result of milk or antacid usage, calcium supplements, or a decrease in its renal excretion such as occurs with thiazide use.^{6,18} Cholecalciferol, available as a rodenticide, can increase the serum $[Ca^{2+}]$ by increasing its release from bone, increasing GI absorption, and decreasing renal elimination. Vitamin D toxicity from excessive vitamin or milk intake also can cause hypercalcemia.⁶⁸ Table 19–9 lists other causes of hypercalcemia.

Symptoms of hypercalcemia consist of lethargy, muscle weakness, nausea, vomiting, and constipation. Life-threatening manifestations include complications from altered mental status such as aspiration pneumonia and cardiac dysrhythmias (Chap. 16). Treatment of clinically significant hypercalcemia focuses on removing the offending xenobiotic when possible,

decreasing GI absorption by administering a binding agent, increasing distribution into bone with a bisphosphonate (onset, 1–2 days), and enhancing renal excretion through forced diuresis with IV 0.9% NaCl solution and furosemide (onset, 4–6 hours).^{6,129} Hemodialysis may be required when significant renal impairment is present.

Xenobiotics more commonly cause hypocalcemia than hypercalcemia. Minor, usually clinically insignificant decreases in serum $[Ca^{2+}]$ can occur in association with anticonvulsant and aminoglycoside therapy.¹⁸ Severe, life-threatening hypocalcemia can occur, however, from ethylene glycol poisoning (Chap. 109) or as a manifestation of fluoride toxicity from either fluoride salts or hydrofluoric acid (Chap. 107).^{34,131} Calcium complex formation with fluoride or oxalate ions is responsible for the rapid development of hypocalcemia in these settings. Similar effects occur with excess phosphate¹³⁴ or citrate^{84,132} intake. This mechanism (calcium complex formation) decreases the ionized $[Ca^{2+}]$ but may or may not reduce the measured total serum $[Ca^{2+}]$. Other xenobiotics that produce hypocalcemia decrease absorption, enhance renal loss, or stimulate calcium entry into cells (Table 19–9).

TABLE 19–9. Xenobiotic Causes of Altered Serum Calcium

<i>Hypocalcemia</i>	<i>Hypercalcemia</i>
Aminoglycosides	All-trans-retinoic acid (ATRA)
Bicarbonate	Aluminum
Bisphosphonates	Androgens
Calcitonin	Antacids (calcium containing)
Citrate	Antacids (magnesium containing)
Edetate disodium	Cholecalciferol and other vitamin D analogs
Ethanol	Lithium
Ethylene glycol	Milk–alkali syndrome
Fluoride	Tamoxifen
Foscarnet	Thiazide diuretics
Furosemide (and other loop diuretics)	Vitamin A
Mithramycin	
Neomycin	
Phenobarbital	
Phenytoin	
Phosphate	
Theophylline	
Valproate	

Symptoms of hypocalcemia consist largely of neuromuscular findings, including paresthesias, cramps, carpopedal spasm, tetany, and seizures. Although ECG abnormalities are common (Chap. 16), life-threatening dysrhythmias are rare. Treatment strategies focus on calcium replacement. When hypomagnesemia or hyperphosphatemia is present, these abnormalities should be corrected or calcium replacement may fail.

Magnesium

Magnesium is the fourth most abundant cation in the body (after Ca^{2+} , Na^{+} , and K^{+}), with a normal total body store of about 2000 mEq in a 70-kg person.¹⁰⁸ Approximately 50% of magnesium is stored in bone, with most of the remainder distributed in the soft tissues. Because only approximately 1% to 2% of magnesium is located in the ECF, serum concentrations correlate poorly with total body stores.¹⁰⁹ Magnesium homeostasis is maintained through dietary intake and renal and GI excretion modulated by hormonal effects.⁵ Clinically significant hypermagnesemia is uncommon in the absence of kidney failure except when massive parenteral infusions of magnesium salts overwhelm renal excretory mechanisms. This has been reported with inadvertent IV infusion,^{17,22,60,92} urologic procedures involving irrigation with magnesium salts,^{39,69} and ingestion of large quantities of magnesium-containing antacids⁸⁶ and cathartics.^{45,49} Of concern is iatrogenic overdose from the use of magnesium-containing cathartics used in poison management.^{47,70,124} In a series of poisoned patients, a single dose of a magnesium-containing cathartic failed to produce any demonstrable rise in serum $[Mg^{2+}]$.¹²⁵ However, patients who received three doses of magnesium sulfate over 8 hours had a significant increase in their serum $[Mg^{2+}]$.¹²⁵ Thus, the potential for iatrogenic toxicity exists, mandating cautious use of magnesium-containing cathartics, especially in patients with renal insufficiency. Table 19–10 lists xenobiotic causes of hypermagnesemia.

TABLE 19–10. Xenobiotic Causes of Altered Serum Magnesium

<i>Hypomagnesemia</i>	<i>Hypermagnesemia</i>
Aminoglycosides	Antacids (magnesium containing)
Amphotericin	Cathartics (magnesium containing)
Cetuximab	Lithium
Cisplatin	Magnesium salts
Citrate	
Cyclosporine	
DDT	
EGFR antibodies (panitumumab and cetuximab)	
Ethanol	
Fluoride	
Foscarnet	
Insulin	
Laxatives	
Loop diuretics	
Methylxanthines	
Osmotic diuretics	
Phosphates	
Proton pump inhibitors	
Strychnine	
Tacrolimus	
Thiazide diuretics	

The symptoms of hypermagnesemia correlate with serum concentrations but depend somewhat on the rate of increase and host factors. At serum $[Mg^{2+}]$ of about 3 to 10 mEq/L, patients feel weak, nauseated, flushed, and thirsty. Bradycardia, a widened QRS complex on ECG, hypotension, and decreased deep tendon reflexes may be noted. As concentration increases, hypoventilation, muscle paralysis, and ventricular dysrhythmias occur. Serum $[Mg^{2+}]$ greater than 10 mEq/L, especially those concentrations greater than 15 mEq/L, often cause death.

Hypermagnesemia should be considered a life-threatening disorder. When significant neuromuscular or ECG manifestations are noted, administration of 5 to 20 mEq of Ca^{2+} intravenously will reverse some of the toxicity.^{6,54} Further therapy should focus on enhancing renal excretion by administering fluids and loop diuretics such as furosemide.⁵⁴ In the presence of renal failure or inadequate renal excretion, hemodialysis will rapidly correct hypermagnesemia.

Xenobiotic-induced hypomagnesemia is common but rarely life threatening. Renal losses (caused by diuretics), GI losses (caused by ethanol), intracellular shifts caused by insulin⁸² or β -adrenergic agonists, and complex formation (by fluoride or phosphate) are common.^{5,6} Table 19–10 lists these and other xenobiotic causes of hypomagnesemia. Of note, many causes of hypomagnesemia also cause hypokalemia and hypocalcemia.⁵ Therefore, when hypomagnesemia is suspected or discovered, the presence of other electrolyte abnormalities should be sought.

The symptoms of hypomagnesemia are lethargy, weakness, fatigue, neuromuscular excitation (tremor and hyperreflexia), nausea, and vomiting.^{25,31} Dysrhythmias may occur, especially in patients treated with cardioactive steroids. Signs and symptoms consistent with hypocalcemia and hypokalemia also may be present.

Treatment involves removing the offending xenobiotic (if it can be identified) and restoring magnesium balance. Although either oral or parenteral supplementation is usually acceptable for mild hypomagnesemia, parenteral therapy is required when significant clinical manifestations are present. When oral therapy is indicated, a normal diet or magnesium oxide, magnesium chloride, or magnesium lactate in divided doses (magnesium 20–100 mEq/d) will often correct the hypomagnesemia.^{5,6} When hypomagnesemia is severe or symptomatic, and kidney function is normal, 16 mEq (2 g) of magnesium sulfate can be given intravenously over several minutes to a maximum of 1 mEq/kg of magnesium in a 24-hour period.^{6,25,67} During any continuous magnesium infusion, frequent serum $[Mg^{2+}]$ determinations should be obtained and the presence of reflexes documented. If hyporeflexia occurs, the magnesium infusion should be discontinued.

SUMMARY

- The management of poisoned or overdosed patients must include an evaluation of their fluid, electrolyte, and acid–base status.
- Developing a stepwise approach to the evaluation of patients with a high anion gap metabolic acidosis is essential.
- The osmol gap can help confirm a suspicion of toxic alcohol poisoning but cannot exclude the diagnosis
- Disorders of sodium (water) are common manifestations of xenobiotic exposure. Since fluid and electrolyte abnormalities may result from both poisoning and the therapy of poisoned patients, reassessment and monitoring are essential to ensure a good clinical outcome.

20 GASTROINTESTINAL PRINCIPLES

Matthew D. Zuckerman and Richard J. Church

Humans are in constant contact with a variety of xenobiotics. In addition to its critical role in absorbing nutrients, the gastrointestinal (GI) tract forms the initial functional barrier between ingested material and the body. An understanding of the GI tract's structure, physiology, and innervation is critical to the toxicologic concepts of absorption, motility, and toxic insult. This chapter discusses the normal role of the GI tract and its relationship to toxicology. Anatomic, pathologic, and microbiologic principles are discussed, including the role of the GI tract in the metabolism of xenobiotics. Examples of GI pathologies and their clinical manifestations are discussed, with examples when appropriate.

STRUCTURE AND INNERVATION OF THE GASTROINTESTINAL TRACT

The luminal GI tract can be divided into five distinct structures: oral cavity and hypopharynx, esophagus, stomach, small intestine, and colon ([Fig. 20–1](#)). These environments differ in luminal pH, specific epithelial cell receptors, and endogenous flora. The transitional areas between these distinct organs have specialized epithelia and muscular sphincters with specific functions and vulnerabilities. Knowledge of the anatomy of these transition zones is particularly important for the localization and management of foreign bodies. The functions of the pancreas and liver are closely integrated with those of the luminal organs. The pancreas is discussed here; the liver and its metabolic functions are discussed in Chaps. 13 and 23.

FIGURE 20–1. Anatomy of the gastrointestinal system. (Modified with permission from Mescher AL: Junqueira’s Basic Histology. 13th ed. New York: McGraw-Hill; 2013.)

The visceral structures of the GI tract are composed of several layers, including the epithelium, lamina propria, submucosa, muscle layers, and serosa (the last of which is only present in intraperitoneal organs). As the transition is made throughout the GI tract, differences in luminal pH, epithelial cell receptors, muscularity, and endogenous flora are encountered, affecting the absorption and metabolism of individual xenobiotics.

The epithelium, the innermost layer of the GI tract, is the most specialized cell type in the intestine and is composed of epithelial, endocrine, and receptor cells. Epithelial cells have polarity, with the basal surface facing the lamina propria and the apical surface facing the lumen. They are further specialized for specific functions of secretion or absorption. Additionally, the epithelial cells form part of the mucosal immune defense, where they are able to detect the presence of

microbial pathogens and downregulate the immune system in the presence of nonpathogenic or probiotic microbes. The major barrier to penetration of xenobiotics and microbes is the GI epithelium, a single-cell-thick membrane. The cell membrane is a semipermeable lipid bilayer that contains aqueous pores through which certain materials can pass, depending on their size or molecular structure. The membrane is not continuous because it consists of individual epithelial cells; however, these cells are joined to each other by structures known as tight junctions. The tight junctions have a gap of about 8 Å, which allows passage only of water, ions, and low-molecular-weight substances.

The muscle layer found beneath the lamina propria is made up of the muscularis mucosa, the circular muscles, and the longitudinal muscles. Contraction of the muscularis mucosa causes a change in the surface area of the gut lumen that alters secretion or absorption of nutrients. Whereas depolarization of circular muscle leads to contraction of a ring of smooth muscle and a decrease in the diameter of that segment of the GI tract, depolarization of longitudinal muscle leads to contraction in the longitudinal direction and a decrease in the length of that segment. The function of the muscle layers is integrated with the enteric nervous system to provide for a coordinated movement of luminal contents through the GI tract so as to maximize absorption and minimize bacterial growth. This integration facilitates the flow of chyme (undigested food) via a coordinated sequence of muscular contractions and relaxations, leading to segmentation of luminal contents, peristaltic movements, and unidirectional flow through the intestine.

The GI tract is innervated by the autonomic nervous system via both extrinsic and intrinsic pathways (Fig. 20–2). The extrinsic innervation permits communication among the brain, spinal cord, and chemoreceptors and mechanoreceptors located in the gut. Parasympathetic stimulation in the extrinsic pathway tends to be excitatory (“rest and digest”) and is carried via the vagus, splanchnic, and pelvic nerves to the myenteric and submucosal plexuses. In contrast, increased sympathetic tone (“fight or flight”) inhibits digestive and peristaltic activity via fibers that originate in the thoracolumbar cord and terminate in the myenteric and submucosal plexuses. The intrinsic innervation of the GI tract, or enteric nervous system, constitutes a reflex arc that modulates both peristalsis (via the myenteric plexus) and secretion (via the submucosal plexus) in response to parasympathetic and sympathetic tone.

FIGURE 20–2. Innervation of the gastrointestinal system. (Adapted with permission from McAninch JW, Lue TF, Smith DR: Smith and Tanagho's General Urology. 18th ed. New York: McGraw-Hill Professional; 2013.)

THE IMMUNE SYSTEM AND MICROBIOLOGY OF THE GASTROINTESTINAL TRACT

An elaborate mucosal immune system has evolved to protect the GI tract from pathogens.⁴⁵ Mucosal immunity can be divided into an afferent limb, which recognizes a pathogen and induces the proliferation and differentiation of immunocompetent cells, and an efferent limb, which coordinates and affects the immune response. The afferent system includes the lymphoid follicles and specialized M-cells found therein that promote transit of antigens to antigen-presenting cells.³⁰ After being sensitized, immune cells undergo a complicated process of clonal expansion and differentiation, which occurs in mucosal and mesenteric lymphoid follicles, as well as in extraintestinal sites. Immunocompetent cells then return to the intestine and other mucous membranes and are scattered diffusely within the epithelial and lamina propria compartments.

The normal endogenous flora in the GI tract includes more than 400 species of bacteria along with a small number of fungi and viruses; the intestinal mucosa is normally colonized by large numbers of nonpathogenic anaerobic strains of *Bacteroides* spp, *Eubacterium* spp, *Clostridium* spp as well as aerobic strains of *Escherichia coli*, *Proteus* spp, *Enterobacter* spp, *Serratia* spp, *Lactobacillus* spp, and *Klebsiella* spp.¹⁸ The concentration of luminal bacteria varies by site, from lowest in the proximal small intestine to highest in the large intestine. En masse, these bacteria are more metabolically active than the liver. Endogenous bacteria occupy unique niches related to host physiology, environmental pressures, and microbial interactions, which result in long-term stability. The flora may be altered by various insults (particularly antibiotics) but usually returns to baseline after the insult is removed. Indeed, the cumulative total of microbial species in the enteric system (or enterotype) is remarkably consistent across countries and continents.²

The endogenous flora has multiple metabolic functions. A primary function in the colon is the salvage of malabsorbed carbohydrates by fermentation and production of short-chain fatty acids, a preferred substrate for colonic epithelial cells. This increased metabolic efficiency is best demonstrated when mice grown in germ-free conditions require a higher caloric intake to maintain weight.³⁷ This has led to some conjecture about the link between human flora and obesity, although this has yet to be born out.

Bacterial metabolism can significantly affect the disposition of enteral compounds. For example, the bacterial metabolism of digoxin contributes to its steady-state concentrations, and antibiotic treatment may reduce or eradicate the intestinal flora, predisposing to digoxin toxicity.⁹ Bacterial contribution to vitamin K metabolism is also demonstrated, necessitating dose adjustments of warfarin during and after antibiotic therapy. The metabolic activity of intraluminal bacteria is exploited in some treatment strategies. For example, sulfasalazine, used in the treatment of ulcerative colitis, is created through the linkage of 5-aminosalicylic acid to sulfapyridine. The azo bonds of the nonabsorbable sulfasalazine are broken by bacterial azoreductases, permitting the absorption of active metabolites in the colon at the site of inflammation.³³

The normal flora of the gut consists of probiotics—live, nonpathogenic bacteria and fungi that can also be used as prophylactic or therapeutic xenobiotics. These bacteria compete for and displace pathogenic bacteria, directly modulate intestinal immune function, and exert a trophic effect on the GI tract. They are used to decrease traveler's diarrhea, suppress antibiotic-induced diarrhea, and reduce inflammation in ileal pouches after colectomy in patients with ulcerative colitis.^{17,19,20}

REGULATORY SUBSTANCES OF THE GASTROINTESTINAL TRACT

There are three groups of regulatory peptide hormones that act on target cells within the GI tract. These are released from endocrine cells in the GI mucosa into the portal circulation and enter the systemic circulation to affect target cells. Gastrin, cholecystokinin (CCK), secretin, and glucose-dependent insulintropic polypeptide (GIP; formerly gastric inhibitory peptide) are considered the primary GI hormones. Somatostatin and histamine make up the paracrines, hormones that are released from endocrine cells and diffuse over short distances to act on target cells located in the GI tract. Vasoactive intestinal peptide (VIP), gastrin-releasing peptide (GRP), and enkephalins compose the last group known as neurocrines; substances that are synthesized in neurons of the GI tract, move by axonal transport down the axon, and are then released by action potentials in the nerves. The effects of these regulators are summarized in [Table 20–1](#).²⁶

TABLE 20–1. Regulatory Substances of the GI Tract

Substance	Site of Secretion or Release	Stimulus for Secretion/Release	Actions
Endocrines			
Gastrin	G cells of gastric antrum	Small peptides and amino acids Stomach distention Vagal stimulation (via GRP) Inhibited by H^+ in stomach (negative feedback)	\uparrow Gastric H^+ secretion \uparrow Growth of gastric mucosa
Cholecystokinin	I cells of duodenum and jejunum	Small peptides and amino acids Fatty acids and monoglycerides	\uparrow Contraction of gallbladder and relaxation of sphincter of Oddi \uparrow Pancreatic enzyme and HCO_3^- secretion \uparrow Growth of exocrine pancreas and gallbladder \downarrow Gastric emptying (allows more time for digestion and absorption)
Secretin	S cells of duodenum	H^+ in duodenal lumen Fatty acids in duodenal lumen	\downarrow Small intestinal H^+ \uparrow Pancreatic HCO_3^- secretion \uparrow Biliary HCO_3^- secretion \downarrow Gastric H^+ secretion \uparrow Growth of exocrine pancreas
GIP	K cells of small intestine	Fatty acids, amino acids, oral glucose	\uparrow Insulin release \downarrow H^+ secretion by gastric parietal cells
Motilin	Epithelial cells of duodenum	Periodic (not responsive to food)	\uparrow Propulsion of smooth muscle
Ghrelin	P/D1 cells of stomach	Fasting	\uparrow Gastric emptying Stimulates feeding
Paracrines			
Somatostatin	D cells throughout GI tract	H^+ in GI tract lumen Inhibited by vagal stimulation	\downarrow Release of all GI hormones \downarrow Gastric H^+ secretion \downarrow Pancreatic secretions \downarrow Splanchnic blood flow
Histamine	Mast cells of gastric mucosa	Vagal stimulation gastrin	\uparrow Gastric H^+ secretion
Nitric oxide	Enteric nerves	Cellular inflammation	\uparrow Epithelial secretion Vasodilation Smooth muscle relaxation
Neurocrines			
VP	GI tract neurons	H^+ in duodenal lumen	Smooth muscle relaxation \uparrow Pancreatic HCO_3^- secretion \uparrow Fluid and electrolyte secretion from intestinal epithelium and bile duct cholangiocytes \downarrow Gastric H^+ secretion
Gastrin-releasing peptide	Vagus nerves that innervate G cells	Vagal stimulation	\uparrow Gastrin release from G cells
Enkephalins (met-enkephalin, leu-enkephalin)	GI tract mucosa and smooth muscle neurons		\uparrow Contraction of GI smooth muscle \downarrow Intestinal secretion of fluid and electrolytes

GIP = glucose-dependent insulinotropic polypeptide (formerly gastric inhibitory peptide); GRP = gastrin-releasing peptide; VP = vasoactive intestinal peptide.

Xenobiotic effects on GI regulation can lead to intended or unintended consequences. Somatostatins reduce splanchnic blood flow and portal blood pressure, leading to their use as therapeutics for bleeding esophageal varices. Erythromycin agonizes motilin receptors, leading to increased GI propulsion, cramping, and diarrhea.

ANATOMIC AND PHYSIOLOGIC PRINCIPLES

Oropharynx and Hypopharynx

The main functions of the mouth and oropharynx are chewing, lubrication of food with saliva, and swallowing. Saliva initiates digestion of starch by α -amylase (ptyalin), triglyceride digestion by lingual lipase, lubrication of ingested food by mucus, and protection of the mouth and esophagus by dilution and buffering of ingested foods.

Saliva production is unique in that it is increased by both parasympathetic and sympathetic activity. Parasympathetic stimulation, via cranial nerves VII and IX, acts on muscarinic cholinergic receptors on acinar and ductal cells, increasing saliva production via vasodilation and increasing transport processes. Parasympathetic pathways are stimulated by food in the mouth, smells, conditioned reflexes, and nausea and are inhibited by sleep, dehydration, and fear. Sympathetic stimulation originates from preganglionic nerves in the thoracic segments T1 to T3. When β -adrenergic receptors are triggered by norepinephrine, production of saliva increases but at a rate less than that of parasympathetic stimulation.¹¹ It is theorized that the hypersalivation, or sialorrhea, associated with clozapine use may be related to agonism of parasympathetic muscarinic receptors or antagonism of adrenergic α receptors (resulting in unopposed β -adrenergic receptor-mediated vasodilation).⁵ Conversely, dysfunction of saliva production, via the anticholinergic side effects of other antipsychotics, can lead to dry mouth, or xerostomia.

Esophagus

The esophagus is a distensible muscular tube that extends from the epiglottis to the gastroesophageal junction. The lumen of the esophagus narrows at several points along its course, first at the cricopharyngeus muscle, then midway down alongside the aortic arch, and then distally where it crosses the diaphragm. The upper esophageal sphincter (UES) and lower esophageal sphincter (LES) are physiologic high-pressure regions that remain closed except during swallowing. Although the LES is a functional segment without anatomic features, the UES is marked by the presence of striated muscle.

The wall of the esophagus reflects the general structural organization of the GI tract noted previously, consisting of mucosa, submucosa, muscularis propria, and adventitia. The mucosal layer has three components. The nonkeratinizing stratified squamous epithelial layer faces the lumen; provides protection for underlying tissue; and houses several specialized cell types such as melanocytes, endocrine cells, dendritic cells, and lymphocytes. The lamina propria is the nonepithelialized portion of the mucosa, and the muscularis mucosa, a layer of longitudinally oriented smooth muscle bundles, is the third component.

The submucosa consists of loose connective tissue, and submucosal glands secrete a mucin-containing fluid via squamous epithelium-lined ducts, which facilitates lubrication of the esophageal lumen. The muscularis propria consists of an inner circular and outer longitudinal coat of smooth muscle; this layer also contains striated muscle fibers in the proximal esophagus that are responsible for voluntary swallowing.

The esophagus has no serosal lining. Only small segments of the intra-abdominal esophagus are covered by adventitia, a sheathlike structure that also surrounds the adjacent great vessels, tracheobronchial tree, and other structures of the mediastinum.

The esophagus provides a conduit for food and fluids from the pharynx to the stomach, and the sphincters generally prevent reflux of gastric contents into the esophagus. Normal transit of food involves coordinated motor activity, including a wave of peristaltic contraction, relaxation of the LES (facilitated by nitric oxide and VIP), and subsequent closure of the LES (facilitated by several hormones and neurotransmitters such as gastrin, acetylcholine, serotonin, and motilin). Xenobiotics can alter muscle tone in various segments of the esophagus, altering function. Caffeine is associated with relaxation of the LES and decreased peristalsis, increasing incidence of acid reflux.²⁹ Additionally, sildenafil, via its effect on nitric oxide, relaxes esophageal smooth muscle, decreasing the pathologically elevated esophageal tone common to patients with achalasia.⁷ Because of the rapid transit time of swallowed substances through this portion of the GI tract, digestion does not take place, and passive diffusion of substances from the food into the bloodstream is prevented.^{11,46}

Stomach

The stomach is a saccular organ covered entirely by peritoneum that has a capacity greater than 3 L. The stomach is divided into five anatomic regions: the cardia, fundus, corpus or body, antrum, and pyloric sphincter. The gastric wall consists of mucosa, submucosa, muscularis propria, and serosa. The interior surface of the stomach is marked by coarse rugae, or longitudinal folds. The mucosa is made up of a superficial epithelial cell compartment and a deep glandular compartment. The glandular compartment consists of gastric glands, which vary between regions of the stomach. The mucus glands of the

cardia, fundus, and body secrete mucus and pepsinogen. Oxyntic, or acid-forming, glands found in the fundus and body contain parietal, chief, and endocrine cells. The parietal cells contain vesicles that house hydrochloric acid–secreting proton pumps and secrete intrinsic factor, a substance necessary for the ileal absorption of vitamin B₁₂. Chief cells secrete the proteolytic proenzyme pepsinogen, which is cleaved to its active form, pepsin, upon exposure to the low luminal gastric pH of 3 to 4. Pepsin is subsequently inactivated in the duodenum when the pH increases to 6.0. The endocrine, or enterochromaffinlike (ECL), cells found in the mucosa of the body of the stomach produce histamine, which increases acid production and decreases gastric pH by stimulating H₂ receptors on the parietal cells. Somatostatin and endothelin, both modulators of acid production, are also produced in ECL cells (Fig. 49–4).

Hydrochloric acid is secreted when cephalic, gastric, and intestinal signals converge on the gastric parietal cells to activate proton pumps and release hydrochloric acid in an adenosine triphosphate–dependent process. During the cephalic phase, or the preparatory phase of the brain for eating and digestion, acetylcholine is released from vagal afferents in response to sight, smell, taste, and chewing. Acetylcholine stimulates the parietal cells via muscarinic receptors, resulting in an increase in cytosolic calcium and activation of the proton pump. G cells, located in the antrum of the stomach, produce and release gastrin in response to luminal amino acids and peptides. Gastrin activates receptors within parietal cells, leading to a similar increase in cytosolic calcium. Additionally, gastrin and vagal afferents induce the release of histamine from ECL cells, which stimulates parietal cell H₂ receptors. Lastly, the intestinal phase is initiated when food containing digested protein enters the proximal small intestine and involves gastrin as well as a number of other polypeptides in the secretion of hydrochloric acid from the stomach⁴⁶ (Fig. 20–3).

FIGURE 20–3. Effects of various xenobiotics on the gastrointestinal tract. CCK-B = cholecystokinin receptor B; ECL cell = enterochromaffinlike cell; H = histamine; H₂ = histamine-2 (H₂) receptor; M₁, M₃ = muscarinic receptors; ST2 = somatostatin-2 receptor.

The gastric mucosa is protected from gastric acidic secretions by several mechanisms, including a thin layer of surface mucus and channels that allow acid- and pepsin-containing fluids to exit glands without contact with the surface epithelium. Additionally, the surface epithelium secretes bicarbonate, raising the pH at the cell surface. Prostaglandins produced in the mucosal cells stimulate production of bicarbonate and mucus, and inhibit parietal cell production of acid; prostaglandin inhibition by nonsteroidal antiinflammatory drugs (NSAIDs) plays an important role in the pathogenesis of peptic ulcer disease.⁴⁶

In the stomach, ingested products are ground to particle sizes of less than 0.2 mm, which are then further processed and digested in preparation for absorption of nutrients in the small intestine. Many xenobiotics are weak acids that are no longer ionized in the acidic environment of the stomach, facilitating absorption through the lipid bilayer at the level of the stomach. Other factors that affect xenobiotic absorption include particle size, transit time, and type of drug delivery system. Different drug formulations, such as time release, enteric coating, slowly dissolving matrices, dissolution control via osmotic pumps, ion exchange resins, and pH-sensitive mechanisms, can affect bioavailability and the site of maximal release within the GI tract.

The time required for gastric emptying is determined by the complex interplay of innervation, muscle action, underlying

illness, and xenobiotic exposure. Digestion and absorption are time-dependent processes, and optimal absorption requires adjustment of the luminal environment through secretion of ions and water, to accommodate meals that vary considerably in nutrient composition, water content, and density. Osmoreceptors and chemoreceptors in the GI tract fine tune the digestive and absorptive processes by regulating transit and secretion using a variety of neurocrine, paracrine, and endocrine mechanisms. Interference with this integrated response may lead to stasis and bacterial overgrowth or rapid transit with decreased absorption and development of diarrhea. A large number of mediators affect motility, including common neurotransmitters, such as acetylcholine and norepinephrine; hormones; cytokines; inflammatory compounds; and others. In general, whereas parasympathetic impulses promote motility, sympathetic stimulation inhibits motility. Other transmitters, such as serotonin, promote transit, but dopamine and enkephalins can slow motility. Some xenobiotics, such as opioids and diphenhydramine, delay gastric emptying, but other xenobiotics, such as metoclopramide, may enhance gastric emptying. Our understanding of the complex neuroendocrine gastric axis continues to evolve in attempts to explain new phenomenon, such as the cannabinoid hyperemesis syndrome, which may be caused by cannabinoid receptors in the brain or gut.⁴¹

Small and Large Intestines

In an average adult, the small intestine is approximately 6 m in length and begins retroperitoneally as the duodenum, becoming intraperitoneal at the jejunum and ileum. The boundary between the small intestine and large intestine is the ileocecal valve, and the large intestine typically measures 1.5 m in an adult. The large intestine (or colon) is further divided into cecal, ascending, transverse, descending, and sigmoid segments. The sigmoid colon is continuous with the rectum and terminates at the anus. Whereas anterograde and retrograde peristalsis occurs in the small intestine, anterograde peristalsis predominates in the large intestine. This movement allows for mixing of food, maximizes contact with the mucosa, and is mediated by both the extrinsic and intrinsic nervous systems. The remarkable absorptive capacity of the small intestine is made possible by innumerable villi of the intestinal wall, which extend into the lumen and increase absorptive area. The epithelial border of the small intestine also contains mucin-secreting goblet cells, endocrine cells, and specialized absorptive cells; functionally, these cells create an ideal environment for nutrient absorption. The mucosa of the large intestine is devoid of villi. The large intestine functions primarily to absorb electrolytes and water, secrete potassium, salvage any remaining nutrients, and store and release waste. Intestinal epithelial cells also metabolize xenobiotics, a function typically attributed to the liver (see below).

Regeneration of injured or senescent intestinal epithelial cells begins in the crypts, with differentiation occurring as these cells migrate toward the intestinal lumen. This process occurs rapidly, with turnover of the small intestinal epithelium occurring every 4 to 6 days and large intestinal epithelium turnover occurring every 3 to 8 days. This rapid regeneration leaves the intestinal epithelium vulnerable to processes that interfere with cell replication (eg, radiation, chemotherapy). Sloughing of GI epithelium, typically manifested by hemorrhagic enteritis, is a valuable marker for xenobiotic insults that lead to mitotic arrest.

Anatomic and functional changes after bariatric surgery and bowel resection have important effects on drug bioavailability and toxicity. The common Roux-en-Y gastric bypass surgery, which diverts gastric contents into distal small bowel, may increase bioavailability by bypassing intestinal CYP3A or decrease bioavailability by bypassing the proximal jejunum as an area of drug absorption.¹⁶ Alterations in stomach and bowel pH after surgery may affect absorption of ionized drugs. Disruption of the enterohepatic recirculation may enhance elimination of drugs such as digoxin.⁴⁸ Many xenobiotics, such as ethanol, oral morphine, and caffeine, achieve maximum serum concentrations faster because of rapid transit. However, studies evaluating serum concentrations of known CYP substrates (caffeine [CYP1A2], tolbutamide [CYP2C9], omeprazole [CYP2C19], and midazolam [CYP3A]) in patients with gastric bypass surgery have not found any clinically significant changes in drug metabolism.⁴³ Because specific data are limited, current recommendations for dosing in postoperative patients are based on extrapolating from a xenobiotic site of absorption and kinetics and a particular patient's functional GI anatomy.

Pancreas

The pancreas is a retroperitoneal organ that serves both exocrine and endocrine functions. The exocrine portion of the gland produces digestive enzymes and occupies more than 80% to 85% of the mass of the pancreas. The exocrine pancreas is composed of acinar cells, specialized epithelial cells housing zymogen granules that release digestive enzymes and proenzymes into the duodenum. Columnar epithelial cells produce mucin and ductal cuboidal epithelial cells secrete a bicarbonate-rich fluid that neutralizes gastric acids. The pancreas secretes 2 to 2.5 L/day of this mixed solution. Typically, the digestive enzymes are released as proenzymes, such as trypsinogen, chymotrypsinogen, and procarboxypeptidase, which are activated upon contact with the higher pH of the duodenum; this process usually helps to prevent autodigestion of the pancreas itself. Enzymes on the brush border of the duodenum, including enteropeptidase, cleave proenzymes to their active forms. Only pancreatic amylase and lipase are secreted in their active forms.

Secretion of pancreatic enzymes is regulated by multiple factors, the most important of which are cholecystokinin and secretin, both produced in the duodenum. Cholecystokinin is released from the duodenum in response to fatty acids and the products of protein catabolism such as peptides and amino acids. Cholecystokinin stimulates acinar cells to release

digestive enzymes and proenzymes. Secretin is released by the duodenum in the presence of lowered pH caused by gastric acids and luminal fatty acids. Secretin triggers ductal cells to secrete bicarbonate and water. Acetylcholine also plays a role in the regulation of pancreatic exocrine function by stimulating digestive enzyme secretion from the acinus and potentiating the effects of secretin. Vagal reflexes increase acetylcholinergic tone in the setting of decreased pH, protein breakdown products, and fatty acids in the duodenal lumen.

The endocrine portion of the pancreas is composed of approximately one million clusters of cells known as the islets of Langerhans that secrete insulin, glucagon, and somatostatin. Other products of the endocrine pancreas include serotonin and VIP. Injury to the endocrine pancreas can result in impaired glucose homeostasis. In one study, more than one third of patients with an episode of alcoholic pancreatitis subsequently developed impaired glucose tolerance.³⁶

XENOBIOTIC METABOLISM

Although the liver is usually identified as the site of xenobiotic metabolism, similar functions occur in the luminal GI tract (including hydroxylation, sulfation, acetylation, and glucuronidation). Biotransformation is a property both of luminal bacteria and enterocytes. Metabolism by the intestine affects the amount of orally administered xenobiotic that actually enters the body and therefore contributes to the first-pass effect, or presystemic disposition.

One of the most well-described families of export proteins, P-glycoprotein (PGP), is found in the mucosa of the small and large intestines, hepatocytes, adrenal cortex, renal tubules, and capillary cells lining the blood–brain barrier.⁴⁹ The PGPs are susceptible to induction and inhibition in a manner similar to hepatic cytochrome oxidase enzymes. Many of the substrates of CYP3A have inhibitory effects on PGPs. Inhibitors of PGPs may raise serum concentrations of a xenobiotic, although inducers of PGPs may prevent therapeutic drug concentrations from ever reaching the target cell. The PGP system is important in drug interactions and drug resistance (Chap. 9).

Pathologic Conditions of the Gastrointestinal Tract

Oral Pathology. Discoloration of the teeth is reported with a number of medications, most notably tetracyclines (Table 20–2). Gingival hyperplasia, overgrowth of the gums around the teeth, is an uncommon adverse effect from chronic use of several xenobiotics. Some medications implicated in causing gingival hyperplasia include calcium channel blockers, cyclosporine, lithium, phenobarbital, phenytoin, topiramate, and valproic acid.¹ Xerostomia, or pathologic dryness of the mouth, is an uncomfortable effect of many xenobiotics that can lead to increased dental decay. The list of xenobiotics that can cause xerostomia is extensive, but the most commonly implicated classes of xenobiotics causing xerostomia are listed in Table 20–3. Chronic methamphetamine use is linked to characteristic oral pathology known as “meth mouth.” This condition, which is common in both inhalational and intravenous users, is characterized by extensive and severe tooth decay and is linked to poor hygiene, bruxism, and xerostomia associated with methamphetamine use.¹²

TABLE 20–2. Xenobiotics Causing Discoloration of the Teeth and Gums¹

Betel	Red
Cadmium	Yellow
Chlorhexidine oral rinse	Brown
Ciprofloxacin	Green
Doxycycline	Yellow
Fluoride	White flecking
Lead	Blue line
Quinine	Blue-gray or blue-black
Silver	Brown-grey to blue-grey
Tetracycline	Yellow to brown-grey

TABLE 20–3. Xenobiotics That Commonly Cause Xerostomia¹

- α₁-Adrenergic receptor antagonists
- α₂-Adrenergic receptor agonists

Anticholinergics
Antidepressants (cyclic antidepressants, maprotiline)
Antihistamines
Antipsychotics (phenothiazines)
Methamphetamine
Protease inhibitors

Esophagitis and Dysphagia. Xenobiotic-induced esophageal injury includes esophagitis (including pill esophagitis), ulceration, perforation, and stricture. The most common presenting complaint is a foreign body sensation in the throat.²³ Xenobiotics commonly implicated in esophagitis and esophageal ulcerations are listed in [Table 20–4](#). Patients with preexisting esophageal motility disorders are at higher risk of esophageal pathology. Additionally, xenobiotics with a gelatin matrix, rapid dissolvability, and large size predispose to esophageal injury. Although most symptoms resolve with withdrawal of the offending xenobiotics, patients with persistent or severe odynophagia should be evaluated with endoscopy to identify pathology and prevent perforation caused by retained pills.¹³

Antipsychotics
Bisphosphonates
Chemotherapeutics
Nonsteroidal antiinflammatory drugs
Potassium chloride
Quinine
Salicylates
Tetracycline

Webs, Strictures, and Esophageal Malignancy. Caustic injury is one of the most common causes of esophageal strictures and malignancies. Some authors have also postulated the role of pill esophagitis in the evolution of esophageal strictures.⁶ As many as 4% of patients with esophageal cancer report a history of caustic injury, and patients with a history of caustic ingestion may have more than a 1000-fold higher risk of developing an esophageal malignancy than the general population.²⁴ Other xenobiotics known to cause esophageal strictures include aluminum phosphide and ionizing radiation.⁴²

Gastritis and Peptic Ulcer Disease. Gastritis, or inflammation of the gastric mucosa, and peptic ulcer disease (PUD) are commonly related to xenobiotic exposure ([Table 20–5](#)). Symptoms of gastritis and PUD include epigastric pain, nausea, and vomiting but may also include hematemesis and melena.³² The primary distinction between gastritis and PUD is appearance at endoscopy: whereas gastritis is characterized by diffuse inflammation of the gastric mucosa, an ulcer is a discrete lesion of the mucosa. NSAIDs remain an important part of the pathogenesis of gastritis and PUD by interfering with prostaglandin synthesis and subsequently impairing the integrity of the gastric mucosal barrier to acid. Cyclooxygenase-2 (COX-2) selective inhibitors promised to decrease the incidence of gastric pathology caused by chronic NSAID use; however, unexpected cardiovascular side effects have limited their utility. New xenobiotics are focusing on inhibition of other inflammatory mediators that may have been previously overlooked, and co-administration of protective xenobiotics. 5-Lipoxygenase (5-LOX) inhibitors may reduce production of proinflammatory leukotrienes, and when co-administered with COX inhibitors, decrease gastric toxicity. Other reformulated NSAIDs are designed to release molecules of NO and H₂S, which help maintain gastric mucosal integrity. These next generation of drugs may preserve systemic antiinflammatory effects while enhancing the gastric safety profile.¹⁰

TABLE 20–5. Xenobiotics Commonly Implicated in Gastritis and Peptic Ulcer Disease

Corticosteroids
Ethanol
Isopropyl alcohol

Nicotine

Nonsteroidal antiinflammatory drugs

Radiation (ionizing)

Salicylates

Chronic treatment of peptic ulcer disease with antacids, H₂ blockers, or proton pump inhibitors can lead to hypochlorhydria or achlorhydria, the reduction or absence of gastric acid, respectively. By increasing the pH of the stomach, these conditions increase risk of bacterial overgrowth, atrophic gastritis, osteoporosis, hip fracture (via impaired calcium absorption), Salmonella and Vibrio cholerae infection, and gastric carcinoma.⁴⁷

Enteritis and Diarrhea. The symptoms of GI distress are nonspecifically associated with xenobiotic exposure. However, certain xenobiotics that increase peristalsis or impair fluid absorption can result in significant diarrhea. Opioid withdrawal, colchicine overdose, and serotonin toxicity are important toxidromes that may feature diarrhea as a prominent symptom. The rapid turnover of the GI mucosa makes it uniquely susceptible to xenobiotics that cause cell death and mitotic arrest. Hemorrhagic enteritis, manifested by hematochezia, can be a characteristic finding of certain exposures (Table 20–6).

TABLE 20–6. Xenobiotic-Induced Enteritis

<i>Mechanism</i>	<i>Xenobiotic</i>
Mechanical irritation	Aloe Bacterial food poisoning Laxatives Mushrooms (GI irritant class)
Cholinergic stimulation	Carbamates Neostigmine, physostigmine , pyridostigmine Mushrooms (muscarine containing) Nicotine Organic phosphorous compounds
Inhibitors of mucosal regeneration (hemorrhagic enteritis)	Arsenic Chemotherapeutics Colchicine Iron Mercuric salts Monochloroacetic acid Podophyllin Pokeweed (<i>Phytolacca americana</i>) Radiation (ionizing)
Mitochondrial poison	Thallium

Bezoars. The term bezoar refers to a concretion formed anywhere in the alimentary system and may be a complication of overdose. The risk of bezoar formation is increased in cases of massive pill ingestion and varies according to tablet size, adhesiveness, and liquid viscosity.⁴⁰ Comorbid illnesses or toxicities that delay gastric emptying and bowel transit time may increase the risk of bezoar formation. Effects from bezoars can range from mechanical obstruction to severe local irritation (and stricture formation) to continuous delayed absorption of xenobiotics and resulting toxicity. Suspicion for bezoar formation is raised in patients after ingestion who develop signs of obstruction (vomiting, abdominal pain, constipation) and in patients with delayed or prolonged toxicity (eg, rising serum iron concentrations 8 hours after ingestion) after overdose.⁴⁰ Depending on the nature of the bezoar, they may be diagnosed using plain radiography; however, in some instances, computed tomography (CT) with oral contrast can increase sensitivity. Recent studies have had limited success with ultrasonography as a diagnostic adjuvant, although this requires further study. Ultimately, a high suspicion of bezoar with negative radiographic evaluation findings may prompt direct visualization with endoscopy and colonoscopy or exploratory surgery. Bezoars frequently require surgical intervention, and several cases report dramatic recovery after removal.

Pancreatitis. Pancreatitis is an acute inflammatory process that results in autolysis of the pancreas from digestive enzymes. Cases range from mild to severe, with an overall mortality rate of 5%.¹⁶ The most common causes of pancreatitis are alcohol abuse and gallbladder disease; however, nonalcoholic xenobiotic-induced pancreatitis accounts for 0.1% to 2% of cases of acute pancreatitis.³ Populations at higher risk of drug-induced pancreatitis include children, women, elderly adults, and patients with HIV and inflammatory bowel disease.³ Acute pancreatitis is defined as having two of the following three criteria: (1) abdominal pain characteristic of acute pancreatitis, (2) serum amylase or lipase greater than three times the upper limit of normal (although amylase is less specific and may be unnecessary), and (3) characteristic findings of acute pancreatitis on CT scan.⁴ The diagnosis of xenobiotic-induced pancreatitis can be impossible to confirm because no diagnostic test or pattern of injury distinguishes xenobiotic-induced pancreatitis from other etiologies. However, the symptoms and laboratory abnormalities associated with xenobiotic-induced pancreatitis tend to resolve shortly after withdrawal of the offending xenobiotic; again, this can be challenging to differentiate from the natural course of mild to moderate disease. It is unclear whether rechallenge with an offending xenobiotic will cause pancreatitis again; however, any xenobiotic suspected of causing pancreatitis should be withheld unless the benefits outweigh this risk. The management of xenobiotic-induced pancreatitis does not differ from other causes and hinges on volume resuscitation, bowel rest, and careful monitoring.

Numerous xenobiotics are associated with pancreatitis, each with varying levels of quality and quantity of evidence; representative xenobiotics are listed in Table 20–7.^{3,21} The pathogenic mechanism varies among xenobiotics. The nucleoside reverse transcriptase inhibitor didanosine and dioxin may promote pancreatitis as a result of mitochondrial injury.^{31,35,38} Cholinergic xenobiotics, such as parathion and certain scorpion venoms, may result in pancreatitis caused by overstimulation.^{25,34} Vasospasm and ischemia are also purported as a mechanism, as in cases of pancreatitis secondary to ergot alkaloids.¹⁴

TABLE 20–7. Xenobiotics Commonly Associated with Pancreatitis^{3,21}

- Alcohols: ethanol and methanol
- Analgesics: acetaminophen, NSAIDs, codeine
- Antibiotics: isoniazid, metronidazole, sulfonamides, tetracycline
- Anticonvulsants: valproic acid, carbamazepine
- Cardiovascular: ACE inhibitors and ARBs, methyldopa
- Dioxin
- Diuretics: loop diuretics
- HIV medications: didanosine, nelfinavir
- HMG-CoA reductase inhibitors
- Hormones: corticosteroids, estrogens
- Hypoglycemics: sitagliptin
- Immunosuppressants: azathioprine, corticosteroids, mesalamine
- Pesticides: organic phosphorous compounds
- Venoms: *Buthus quiquestriatus*, *Tityus discrepans*

ACE = angiotensin-converting enzyme; ARB = angiotensin II receptor blocker; NSAID = nonsteroidal antiinflammatory drug.

The endocrine functions of the pancreas are also susceptible to injury from pancreatitis or toxic insult. Typically, this results from injury to pancreatic β cells leading to impaired glucose homeostasis, similar to diabetes. Streptozotocin is notable for its toxicity to pancreatic β cells and ability to induce diabetes in animal models. In one study of patients after episodes of alcoholic pancreatitis, more than one third developed impaired glucose tolerance.³⁶ There are rare xenobiotics that can cause damage to α cells in animal models; however, they do not consistently cause hypoglycemia (Table 20–8).

TABLE 20–8. Xenobiotics Associated with Endocrine Pancreatic Dysfunction

<i>α Cells</i>	
Cobalt salts	Decamethylene diguanidine
<i>β Cells</i>	
Alloxan	Glucocorticoids
Androgens	Growth hormone
Cyclizine	Pentamidine
Cyproheptadine	Somatostatin
Diazoxide	Streptozocin
Epinephrine	Sulfonamides
Glucagon	Vacor

Constipation. Decreased stooling (fewer than three bowel movements a week) associated with abdominal pain is a major source of morbidity for patients taking opioids and other drugs that slow gastric emptying and decrease gut motility. It is estimated that opioid-induced bowel dysfunction affects up to 40% of patients on long-term opioids.⁸ In its most extreme form, severe constipation is associated with bowel obstruction and perforation. Novel therapeutics for this include locally acting opioid receptor antagonists (eg, prolonged-release naloxone and methylnaltrexone) that may alleviate GI effects without decreasing analgesic effects.¹⁵

Foreign Bodies

The esophagus is the most common site of impaction from symptomatic foreign bodies. They tend to be found just proximal to a pathologic esophageal narrowing or in one of three anatomic places: at the cervical esophagus near the cricopharyngeus muscle, at the level of the aortic notch, or just above the gastroesophageal junction. The likelihood that a foreign object will lodge in the esophagus is related to its size and shape. The major complications of foreign bodies in the esophagus include pain, bleeding, obstruction, or perforation, which may lead to subsequent mediastinitis or fistula. The general rule is that conservative means can be used for up to 12 hours after ingestion of the esophageal foreign body. If serial radiographs demonstrate no movement after 12 hours, endoscopic retrieval or surgery should be considered because the risk of perforation increases after that time; some authors extend this observation period to 24 hours.²² Ingestion of button batteries proves an important exception to this rule. Esophageal button batteries can cause significant mucosal injury in 2 to 4 hours, with perforation in as little as 6 hours.²⁸ Proposed mechanisms for the rapid development of esophageal injury include alkaline burn, local current, and pressure necrosis.²⁸ Most recently, almost all button battery ingestions associated with serious or fatal outcomes were 20-mm lithium batteries, dangerous for their large size and higher voltage.^{27,28,39} Of note, lithium batteries do not contain an alkali solution, lending support to the concept that electrical current results in morbidity rather than leakage of caustic battery contents. All suspected esophageal button batteries should therefore undergo immediate endoscopic removal within 2 hours; success rates with this modality are reported as excellent. Button batteries that are in the stomach or beyond may be left to pass spontaneously in asymptomatic patients.

Foreign bodies are also commonly found in the stomach. Many small foreign bodies pass through the stomach and the remainder of the GI tract without difficulty. Objects greater than 5 cm in length or 2 cm in diameter may be unable to traverse the duodenum and may require endoscopic or surgical removal. Foreign bodies beyond the duodenum may not require any intervention except observation; however, some objects may become lodged at the ileocecal valve. Serial examinations and radiographs can be appropriate for asymptomatic patients; however, increasing abdominal pain or tenderness may mandate further imaging and surgical consultation. Recent increase in pediatric ingestion of strong, small magnets may be one exception to these recommendations. Multiple magnets may attract across bowel walls, preventing transit and leading to intestinal perforation. Ingestion of a single magnet may not increase morbidity and may be managed as above, but the ingestion of multiple magnets should be managed aggressively with surgical consultation for removal.⁴⁴ Body packers represent an unusual exception to these rules. Patients who are discovered to be internally concealing large quantities of illicit drugs may require whole-bowel irrigation to facilitate transit of colonic packets and even emergency laparotomy for obstruction or suspected packet rupture in cases of cocaine or methamphetamine smuggling³⁹ (Special Considerations: SC5).

SUMMARY

- The GI tract is vulnerable to a wide variety of pathogenic organisms.

- The GI tract modulates absorption and metabolism of xenobiotics.
- Endogenous flora contribute greatly to the function and pathology of the GI tract with both host and microbial components acting as one organ system.
- The GI tract involves a complex interplay of regulatory hormones.
- As function follows structure, effects of various xenobiotics are often related to the specific parts of the GI tract that are affected.

21 GENITOURINARY PRINCIPLES

Jason Chu

The genitourinary system encompasses two major organ systems, the reproductive and the urinary systems. Successful reproduction requires interaction between two sexually mature individuals. Xenobiotic exposures to either individual can have an adverse impact on fertility, which is the successful production of children, and fecundity, which is an individual’s or a couple’s capacity to produce children. The role of occupational and environmental exposures in the development of infertility is difficult to define.^{14,41,95,99} Well-designed and conclusive epidemiologic studies are lacking because of the following factors: laboratory tests used to evaluate fertility are relatively unreliable, clinical endpoints are unclear, xenobiotic exposure is difficult to monitor, and indicators of biologic effects are imprecise. Although the negative impact of xenobiotics on fertility is often ignored, infertility evaluations are incomplete without a thorough xenobiotic and occupational history. Differences in the toxicity of xenobiotics in individuals may be sex or age related (or both). Xenobiotic-related, primary infertility may be the result of effects on the hypothalamic–pituitary–gonadal axis or a direct toxic effect on the gonads.⁸² Fertility is also affected by exposures that cause abnormal sexual performance. [Table 21–1](#) lists xenobiotics associated with infertility.

TABLE 21–1. Xenobiotics Associated with Infertility

<i>Men</i>	
<i>Xenobiotic</i>	<i>Effects</i>
Anabolic steroids	↓ LH, oligospermia
Androgens	↓ Testosterone production
Benzene	Chromosomal aberrations in sperm
Chemotherapeutics	Gonadal toxicity
Chlorambucil	Oligospermia
Combination chemotherapy (CVP, MOPP, MVPP)	Oligospermia
Cyclophosphamide	Oligospermia
Methotrexate	Oligospermia
Carbon disulfide	↓ FSH, ↓ LH, ↓ spermatogenesis
Chlordecone	Asthenospermia, oligospermia
Gimetidine	Oligospermia
DBCP	Azospermia, oligospermia
Diethylstilbestrol	Testicular hypoplasia
Ethanol	↓ Testosterone production, Leydig cell damage, asthenospermia, oligospermia, teratospermia
Ethylene oxide	Asthenospermia (in monkeys), oligospermia
Glycol ethers	Azoospermia, oligospermia, testicular atrophy
2-Ethoxyethanol	
2-Methoxyethanol	
Opioids	↓ LH, ↓ testosterone
Lead	↓ Spermatogenesis, asthenospermia, teratospermia
Nitrofurantoin	↓ Spermatogenesis
PCBs	↓ Sperm motility
Radiation (ionizing)	↓ Spermatogenesis
Sulfasalazine	↓ Spermatogenesis
Tobacco	↓ Testosterone
<i>Women</i>	
<i>Xenobiotic</i>	<i>Effects</i>
Chemotherapeutics	Gonadal toxicity
Cyclophosphamide	Ovarian failure
Busulphan	Amenorrhea
Combination chemotherapy (MOPP, MVPP)	Amenorrhea
Diethylstilbestrol	Spontaneous abortions
Ethylene oxide	Spontaneous abortions
Lead	Spontaneous abortions, still births
Oral contraceptives	Affect hypothalamic–pituitary axis, end-organ resistance to hormones, amenorrhea
Thyroid hormone	↓ Ovulation

CVP = cyclophosphamide, vincristine, and prednisone; DBCP = dibromochloropropane; FSH = follicle-stimulating hormone; LH = luteinizing hormone; MOPP = Mustargen, Oncovin, procarbazine, and prednisone; MVP = mustine, vinblastine, procarbazine, and prednisolone; PCB = polychlorinated biphenyl.

Aphrodisiacs are used to heighten sexual desire and to counteract sexual dysfunction. Humans have long sought the

perfect aphrodisiac. However, of those tried, their effectiveness is variable, and toxic consequences occur commonly. Particularly popular are the various treatments for male sexual dysfunction, or erectile dysfunction.

Although many people search for a cure for impotence or infertility, others explore xenobiotics that can be used as abortifacients. Routes of administration used include oral, parenteral, and intravaginal, with an end result of pregnancy termination. However, many of these xenobiotics produce systemic toxic effects on the mother and a nonaborted fetus.

This chapter examines these issues, as well as the impact of xenobiotics on the urinary system, specifically, urinary retention and incontinence, and abnormalities detected in urine specimens. Renal ([Chap. 28](#)), reproductive ([Chap. 31](#)), and carcinogenic principles are discussed elsewhere in this text.

MALE FERTILITY

Male fertility is dependent on a normal reproductive system and normal sexual function. The male reproductive system is composed of the central nervous system (CNS) endocrine organs and the male gonads. The hypothalamus and the anterior pituitary gland form the CNS portion of the male reproductive system. Both organs begin low-level hormone secretion as early as in utero gestation. At puberty, the hypothalamus begins pulsatile secretion of gonadotropin-releasing hormone (GnRH). This stimulates the anterior pituitary gland to release follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in a similarly pulsatile fashion. The hormones exert their effects on the male target organs, inducing spermatogenesis and secondary body sexual characteristics.

Disruption of normal function of any part of the system affects fertility. A number of xenobiotics can adversely affect the male reproductive system and sexual function as shown in [Fig. 21-1](#).

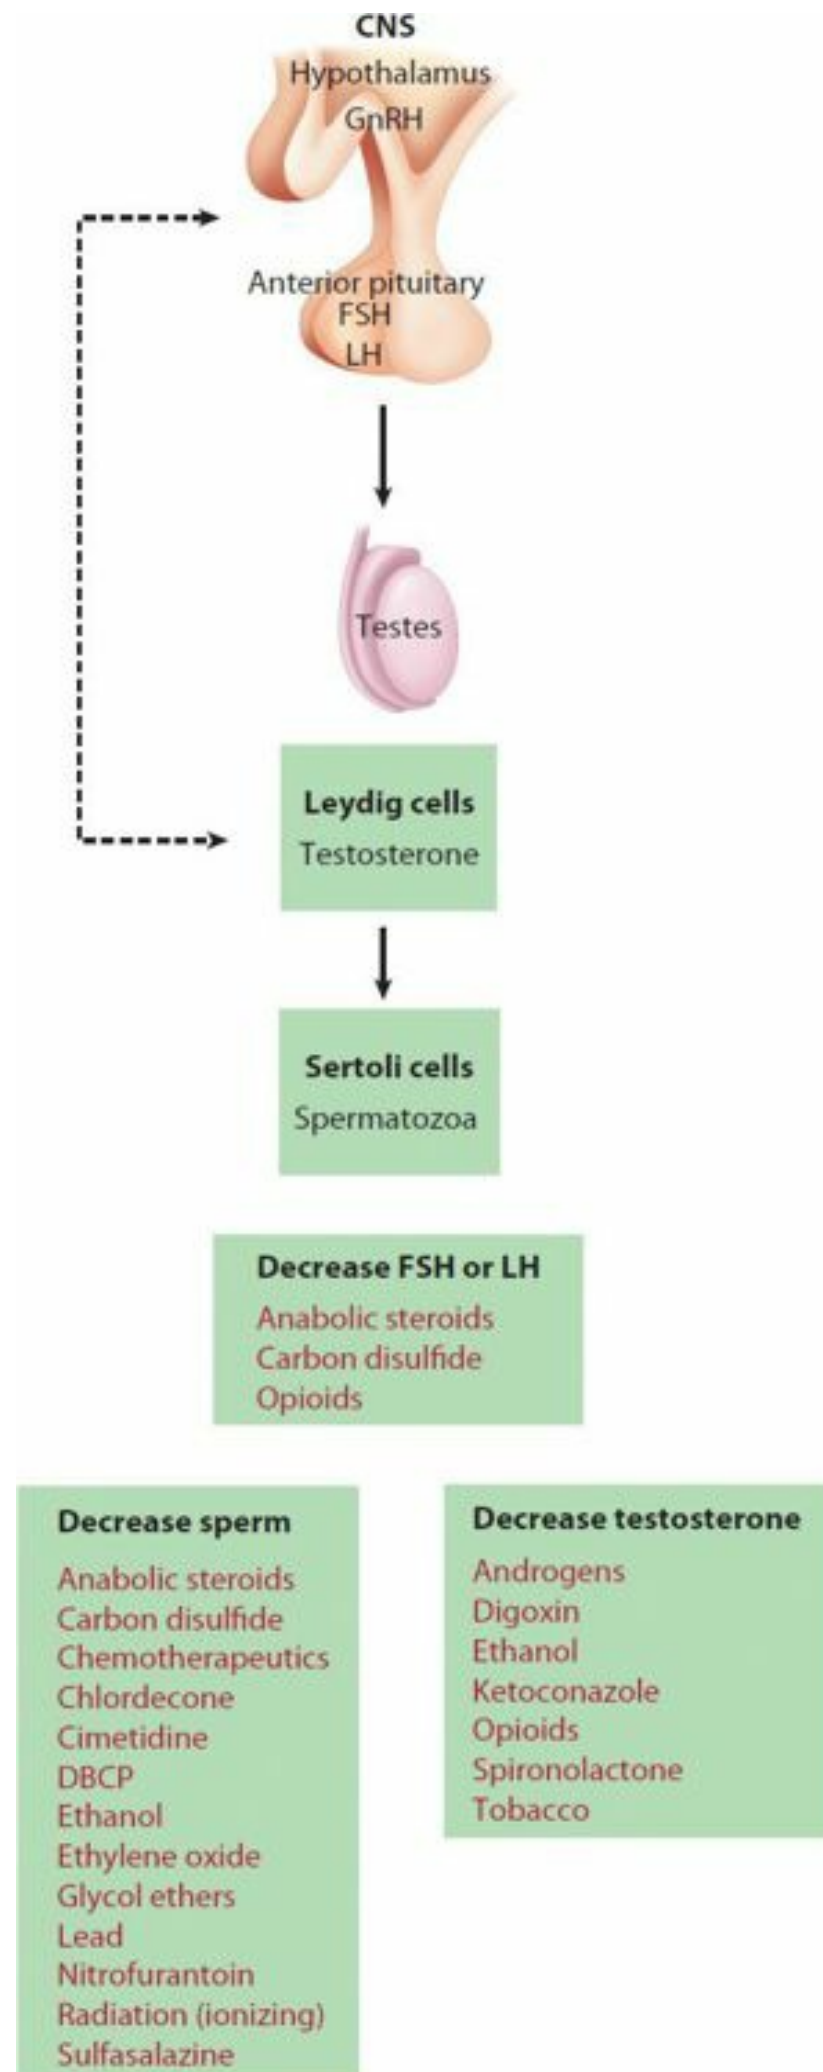

FIGURE 21–1. Schematic of the male reproductive axis and sites of xenobiotic effects. CNS = central nervous system; DBCP = dibromochloropropane; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone.

Spermatogenesis

Central to the male reproductive system is the process of spermatogenesis, which occurs in the testes. The bulk of the testes consist of seminiferous tubules with germinal spermatogonia and Sertoli cells. The remainder of the gonadal tissue is interstitium with blood vessels, lymphatics, supporting cells, and Leydig cells. Spermatogenesis begins with the maturation and differentiation of the germinal spermatogonia. The process is controlled by the secretion of GnRH from the hypothalamus, which stimulates the pituitary to release FSH and LH. FSH stimulates the development of Sertoli cells in the testes, which are responsible for the maturation of spermatids to spermatozoa. LH promotes production of testosterone by Leydig cells. Testosterone concentrations must be maintained to assure the formation of spermatids.²⁴ Both FSH and testosterone are required for initiation of spermatogenesis, but testosterone alone is sufficient to maintain the process.

Testicular Xenobiotics. Xenobiotics can affect any part of the male reproductive tract, but invariably, the end result is decreased sperm production defined as oligospermia, or absent sperm production, azoospermia. In contrast to oogenesis in women, spermatogenesis is an ongoing process throughout life that can be inhibited by decreases in FSH or LH or by Sertoli cell toxicity. Spermatogenic capacity is evaluated by semen analysis, including sperm count, motility, sperm morphology, and penetrating ability. Normal sperm count is greater than 40 million sperm/mL semen, and a count less than 20 million/mL is indicative of infertility.²⁴ Decreased motility (asthenospermia) less than 40% of normal or abnormal morphology (teratospermia) of greater than 40% of the total number of sperm also indicates infertility.^{24,108}

Physiology of Erection. The penis is composed of two corpus cavernosa and a central corpus spongiosum. The internal pudendal arteries supply blood to the penis via four branches. Blood outflow is via multiple emissary veins draining into the dorsal vein of the penis and plexus of Santorini. Within the penis, the corpora cavernosa share vascular supply and drainage because of extensive arteriolar, arteriovenous, and sinusoidal anastomoses.¹²⁸ When penile blood flow is greater than 20 to 50 mL/min, erection occurs. Maintenance of tumescence occurs with flow rates of 12 mL/min. The tunica albuginea limits the absolute size of erection.

In the flaccid state, sympathetic efferent nerves maintain arteriole constriction primarily through norepinephrine-induced α -adrenergic agonism. Whereas α -adrenergic receptor agonism in the erectile tissues decreases cyclic adenosine monophosphate (cAMP) to produce flaccidity, α -adrenergic antagonism can result in pathologic erection (priapism) as a consequence of parasympathetic dominance.¹²⁸ Other vasoconstrictors, such as endothelin, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), and thromboxane A_2 , play a role in maintaining corpus cavernosal smooth muscle tone in contraction, which results in a flaccid state.⁹⁰

Normal penile erection is a result of both neural and vascular effects. Psychogenic neural stimulation arising from the cerebral cortex inhibits norepinephrine release from thoracolumbar sympathetic pathways, stimulates nitric oxide (NO) and acetylcholine release from sacral parasympathetic tracts, and stimulates acetylcholine release from somatic pathways.⁹⁰ Reflex stimulation can also occur from the sacral spinal cord. The afferent limb of the reflex arc is supplied by the pudendal nerves and the efferent limb by the nervi erigentes (pelvic splanchnic nerves).

The central impulses stimulate various neurotransmitters to be released by peripheral nerves in the penis. Nonadrenergic–noncholinergic nerves and endothelial cells produce NO, which is the principal neurotransmitter mediating erection. NO activates guanylate cyclase conversion of guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). Increasing concentrations of cGMP act as a second messenger, mediating arteriolar and trabecular smooth muscle relaxation to enable increased cavernosal blood flow and penile erection.⁹⁰ Both cGMP and cAMP pathways mediate smooth muscle relaxation. Cholinergic nerves release acetylcholine, which stimulates endothelial cells via M_3 receptors to produce NO and prostaglandin E_2 (PGE_2). PGE_2 and nerves containing vasoactive intestinal peptide (VIP) and calcitonin gene-related peptide (CGRP) increase cellular cAMP to potentiate smooth muscle relaxation.

Penile corpus cavernosal smooth muscle relaxation allows increased blood flow into the corpus cavernosal sinusoids. Expansion of the sinusoids compresses the venous outflow and enables penile erection (Fig. 21–2).

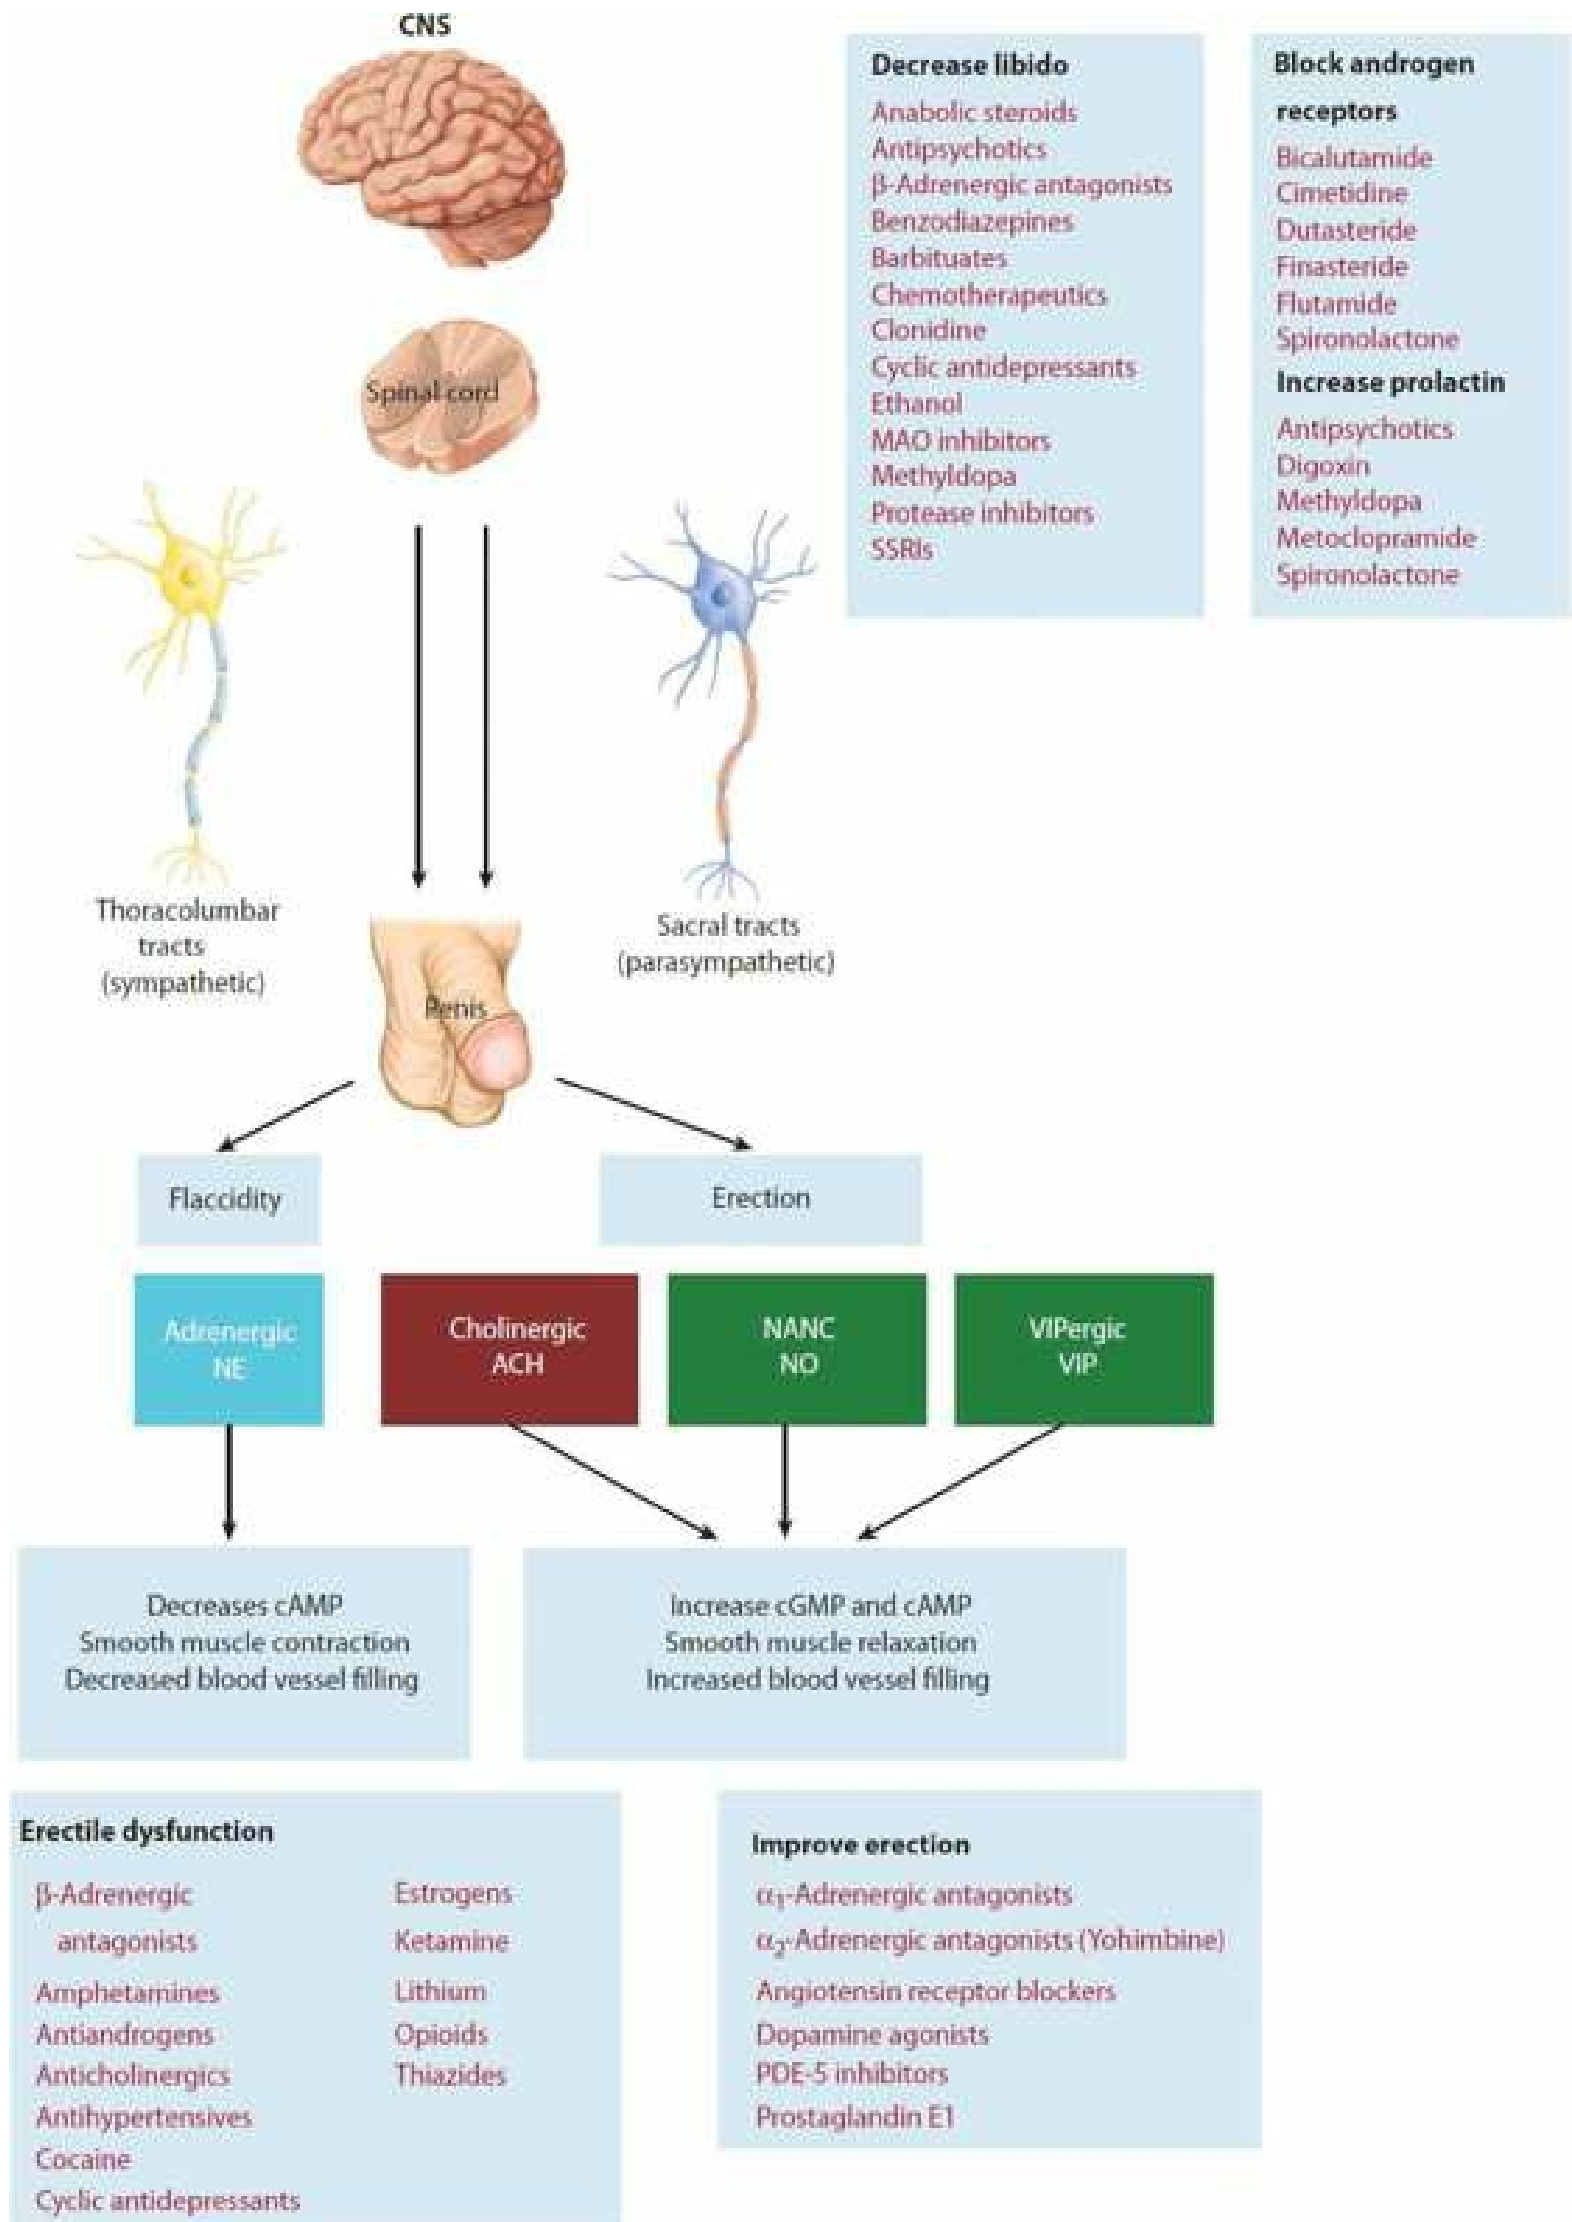

FIGURE 21–2. Schematic of the erection and xenobiotics that cause sexual dysfunction. ACH = acetylcholine; cAMP = cyclic adenosine monophosphate; cGMP = cyclic guanosine monophosphate; MAOI = monoamine oxidase inhibitor; NANC = nonadrenergic-noncholinergic; NE = norepinephrine; NO = nitric oxide; PDE = phosphodiesterase; VIP = vasoactive intestinal peptide; SSRI = selective serotonin reuptake inhibitor.

Sexual Dysfunction

Male sexual dysfunction can result from decreased libido (sexual desire), impotence, diminished ejaculation, and erectile dysfunction. Dopamine, norepinephrine, oxytocin, and adrenocorticotrophic hormone (ACTH) are central neurotransmitters and hormones that facilitate sexual function. Serotonin, prolactin, endogenous opioids, and GABA (γ-aminobutyric acid) inhibit sexual function centrally.³ Libido can be decreased by xenobiotics that block central dopaminergic or adrenergic pathways or by xenobiotics that increase serotonin or prolactin concentrations. Conversely, xenobiotics that increase dopamine can improve sexual function. Sexual dysfunction can also be caused by xenobiotics that decrease testosterone production and by xenobiotics that produce dysphoria. Xenobiotics that affect spinal reflexes can cause diminished ejaculation and erectile dysfunction.¹²⁶

Approximately 30 million men in the United States have erectile dysfunction, with an increased prevalence in older men.⁶ Erectile dysfunction is defined as the inability to achieve or maintain an erection for a sufficiently long period of time to permit satisfactory sexual intercourse⁶ and is divided into the following classifications: psychogenic, vasculogenic, neurologic, endocrinologic, and xenobiotic induced. Xenobiotic-induced erectile dysfunction is associated with the following categories of xenobiotics: antidepressants, antipsychotics, centrally and peripherally acting antihypertensives, CNS depressants, anticholinergics, exogenous hormones, antibiotics, and antineoplastics.^{76,107,126} Treatment of this disorder is varied and includes vacuum-constriction devices, penile prostheses, vascular surgery, and medications that can be administered via the intracavernosal, transdermal, and oral routes.

Antihypertensives. Erectile dysfunction is reported as an adverse effect with all antihypertensives and may be caused, in part, by a decrease in hypogastric artery pressure, which impairs blood flow to the pelvis.¹²⁶ Methyldopa and clonidine both are centrally acting α₂-adrenergic agonists that inhibit sympathetic outflow from the brain. Sexual dysfunction is reported in 26% of patients receiving methyldopa and in 24% of patients receiving clonidine.^{18,93} Erectile dysfunction associated with thiazide diuretics may be related to decreased vascular resistance, diverting blood from the penis.²⁵ Spironolactone acts as an antiandrogen by inhibiting the binding of dihydrotestosterone to its receptors. Impotence related to use of β-adrenergic antagonists is well documented^{5,59,122} and may be caused by unopposed α-adrenergic-mediated vasoconstriction resulting in reduced penile blood flow.

Ethanol. Ethanol is directly toxic to Leydig cells. Chronic ethanol abuse causes decreased libido and erectile dysfunction and is associated with testicular atrophy. In people with alcoholism, liver disease contributes to sexual dysfunction resulting from decreased testosterone and increased estrogen production or decreased breakdown. People with alcoholism can have autonomic neuropathies affecting penile nerves and subsequent erection. Heavy drinkers have more erectile dysfunction than episodic drinkers.¹²⁵

Antidepressants and Antipsychotics. Individuals who take antipsychotics therapeutically have varying degrees of sexual dysfunction related to their underlying disease and their medications. All psychoactive medications are associated with sexual dysfunction to some degree. Monoamine oxidase inhibitors (MAOIs), cyclic antidepressants (CAs), antipsychotics, and selective serotonin reuptake inhibitors (SSRIs) are associated with decreased libido and erectile dysfunction in men.³⁵ Thioridazine is associated with significantly lower LH and testosterone concentrations in men in comparison with other antipsychotics.²⁴ Antidepressants such as bupropion, nefazodone, mirtazapine, and duloxetine have lower incidences of sexual dysfunction in comparison with other antidepressants.¹⁰⁹ Table 21–2 lists xenobiotics associated with sexual dysfunction.

^aAssociated with erectile dysfunction.

Xenobiotics Used in the Treatment of Erectile Dysfunction

Intracavernosal Agents. The three most commonly used intracavernosal agents used for erectile dysfunction are papaverine, PGE₁, and phentolamine. Papaverine is a benzylisoquinoline alkaloid derived from the poppy plant *Papaver somniferum*. It exerts its effects through nonselective inhibition of phosphodiesterase (PDE), leading to increased cAMP and cGMP concentrations and subsequent cavernosal vasodilation. Papaverine was used for the treatment of cardiac and cerebral ischemia but had limited efficacy. Presently, it is used as intracavernosal therapy for erectile dysfunction alone or

in conjunction with phentolamine. Systemic adverse effects include dizziness, nausea, vomiting, hepatotoxicity, metabolic acidosis with elevated lactate concentration with oral administration, and cardiac dysrhythmias with intravenous use. Intracavernosal administration is associated with penile fibrosis, which is usually a dose-related phenomenon, although fibrosis can also occur with limited use.³⁷ More concerning is the development of priapism with papaverine use.

Prostaglandin E₁ (Alprostadil) is a nonspecific agonist of PG receptors resulting in increased concentrations of intracavernosal cAMP, cavernosal smooth muscle relaxation, and penile erection. It is effective via intracavernosal administration as monotherapy. Other preparations include an intraurethral preparation, which is less effective, and a topical gel formulation.⁵⁶ Penile fibrosis can occur, but the incidence is lower compared with papaverine. Other adverse effects include penile pain, secondary to its effects as a nonspecific PG receptor agonist, and priapism.

Phentolamine is a competitive α -adrenergic antagonist at both α_1 and α_2 receptors. It effects erection by inhibiting the normal resting adrenergic tone in cavernosal smooth muscle, thus allowing increased arterial blood flow and erection. Intracavernosal use can cause hypotension, reflex tachycardia, nasal congestion, and gastrointestinal (GI) upset. Penile fibrosis and priapism are also reported.

Oral Agents. Since the development of the PDE-5 inhibitors, oral therapy has replaced intracavernosal injections as the mainstay for treatment of erectile dysfunction. Sildenafil was the first drug developed followed by vardenafil and tadalafil. These medications share a mechanism of action but differ in their pharmacokinetics. PDE-5 inhibitors increase NO-induced cGMP concentrations by preventing PDE breakdown of cGMP, enhancing NO-induced vasodilation to promote penile vascular relaxation and erection.²³

After oral administration, sildenafil is rapidly absorbed with a bioavailability of 40% and a median peak serum concentration of 60 minutes. Its mean volume of distribution is 105 L, and its elimination half-life is 3 to 5 hours. Metabolism is primarily by the CYP3A4 pathway with some minor metabolic activity via the CYP2C9 pathway. Serum concentrations of sildenafil are increased in patients older than 65 years as well as those with hepatic dysfunction or severe kidney disease (creatinine clearance <30 mL/min) and when used with CYP3A4 inhibitors (macrolide antibiotics, cimetidine, antifungal agents, protease inhibitors).³¹

Vardenafil has more selective inhibition of PDE-5 and less inhibition of PDE-6 compared with sildenafil. After oral administration, it has a 14% bioavailability, a volume of distribution of 208 L, a median peak serum concentration of 60 minutes and an elimination half-life of 4 to 5 hours. The CYP3A4 pathway is the primary hepatic metabolic pathway with minor contributions from CYP3A5 and CYP2C9 isoenzymes.^{17,20} The primary metabolite, M1, has PDE-5 inhibitory activity but is four times less potent than vardenafil.²⁰ As with sildenafil, vardenafil concentrations are increased in patients older than 65 years, and those with hepatic dysfunction or severe kidney disease (creatinine clearance <30 mL/min) and when used with CYP3A4 inhibitors (macrolide antibiotics, cimetidine, antifungal agents, protease inhibitors).⁶⁴

Tadalafil has a median peak serum concentration of 2 hours and a mean elimination half-life of 17.5 hours. It is predominantly metabolized by CYP3A4 isoenzymes. Unlike sildenafil and vardenafil, serum concentrations are not affected by age, hepatic dysfunction, kidney disease, or CYP3A4 inhibitors. However, the Food and Drug Administration (FDA) has issued recommendations to decrease the dosage of all PDE-5 inhibitors if used in conjunction with atazanavir.⁷

The most common adverse effects of the PDE-5 inhibitors are headache, flushing, dyspepsia, and rhinitis, which are related to PDE-5 inhibitory effects on extracavernosal tissue.⁵⁵ Blurred vision, increased light perception, and transient blue-green tinged vision are also reported and are related to the weak PDE-6 inhibition of sildenafil in the retina.⁵⁵ Vardenafil and tadalafil are associated with infrequent abnormal vision, including blurred and abnormal color vision.⁵⁷

More serious adverse effects of PDE-5 inhibitors include myocardial infarction, when used alone or with nitrates; subaortic obstruction; stroke; transient ischemic attack; priapism; and hearing loss.^{12,44,63,84,110,114} PDE-5 inhibitors are associated with adverse bleeding events, including epistaxis, variceal bleeding, intracranial hemorrhages, and aortic dissection. The FDA updated the labeling of the PDE-5 inhibitors warning of possible vision loss after reported cases of nonarteritic ischemic optic neuropathy (NAION) associated with PDE-5 inhibitor use.^{9,21,44}

When taken alone, the vasodilatory effects of PDE-5 inhibitors cause a modest decrease in systemic blood pressure. However, because of their mechanism of action via cGMP inhibition and vascular vasodilation, PDE-5 inhibitors can have synergistic interactions with the vasodilatory effects of nitrates, resulting in profound hypotension.^{23,65} A study of healthy male volunteers taking sildenafil demonstrated significantly less tolerance to a nitroglycerin infusion in comparison with placebo.¹²³ Because of this interaction, patients with acute myocardial ischemic syndromes using PDE-5 inhibitors should avoid taking organic nitrates as well.³¹ α_1 -Adrenergic antagonists are also contraindicated with concomitant PDE-5 inhibitor use because of increased hypotensive effects.⁶⁵ Hypotension occurred in patients using vardenafil in combination with terazosin and tamsulosin⁶⁵ and in patients using tadalafil with doxazosin.⁶⁶ However, patients using tadalafil with tamsulosin did not develop hypotension.⁶⁶

Yohimbine, an indole alkylamine alkaloid from the West African yohimbe tree (*Corynanthe yohimbe*), is an α_2 -

adrenergic antagonist with cholinergic activity used to treat erectile dysfunction and postural hypotension associated with anticholinergic drugs.⁷³ It is structurally similar to reserpine. Other names for yohimbine include Aphrodyne, corynine, hydroaergotocin, quebrachine, and the street name “yo-yo.”⁷⁴ Its use in the treatment of impotence is based on the theory that erection is linked to cholinergic stimulation and α_2 antagonism, resulting in an increase inflow and decrease outflow of blood to the penis. Although the agent Aphrodex, which contained 5 mg of yohimbine, 5 mg methyltestosterone, and 5 mg strychnine, improved performance in men with erectile failure,⁷⁷ its distribution was halted in 1973 because of safety concerns.¹⁰⁵

Yohimbine can be obtained by prescription, but extracts are also available in “health food” products marketed as “vitalizing agents for men and women.”³⁹ Yohimbine can also be extracted from the Rauwolfia root.⁴⁹ The “therapeutic” dose is 2 to 6 mg three times daily. The drug is rapidly absorbed, with peak serum concentrations occurring in 45 to 60 minutes. The half-life is 36 minutes, and clearance is by hepatic metabolism without renal excretion.⁹⁶ Maximum pharmacologic effects occur 1 to 2 hours after ingestion, and effects persist for 3 to 4 hours.⁷⁴

Because the erectile process involves various neurotransmitters, a single xenobiotic would be expected to only have a partial effect. In a double-blind study of 100 men with erectile failure treated with 18 mg/d of yohimbine, 42.6% of the treatment group and 27.6% of the placebo group reported some improvement in erectile function, which was not statistically significant.⁸⁹ Another study that compared a higher dose of yohimbine and placebo in 82 elderly men showed a statistically significant improvement with treatment.¹¹⁶

Adverse effects can occur with relatively low doses of yohimbine. Tachycardia, hypertension, mydriasis, diaphoresis, lacrimation, salivation, nausea, vomiting, and flushing can occur after intravenous administration.⁶⁰ Ten milligrams of yohimbine can elicit manic symptoms in patients with bipolar disorder,¹⁰² and 15 mg/d is associated with bronchospasm⁶⁸ and a lupuslike syndrome.¹⁰⁶ A 16 year-old woman who ingested 250 mg of yohimbine powder, purchased for its purported aphrodisiac activity, developed an acute dissociative reaction with weakness, paresthesias, headache, nausea, palpitations, and chest pain. She also developed tachycardia, tachypnea, diaphoresis, tremors, and a rash. Her symptoms resolved after 36 hours without treatment.⁷⁴ Another report describes a 62 year-old man who ingested 200 mg of yohimbine and developed tachycardia, hypertension, and a brief period of anxiety that resolved without treatment.⁴⁹ Symptomatic patients who ingest yohimbine should receive activated charcoal and should be observed until asymptomatic. Clonidine has been recommended for treatment of yohimbine’s central and peripheral effects.⁷⁴ β -Adrenergic antagonists may attenuate some of the peripheral toxicity but may also result in unopposed α_1 -adrenergic activity and worsening of hypertension and should be avoided. Benzodiazepine administration may be sufficient for the treatment of agitation and sympathomimetic effects related to yohimbine.

Sublingual apomorphine effects erection through activation of central dopaminergic pathways, most likely D₂ receptors in the paraventricular nucleus of the hypothalamus.⁵⁸ It reaches maximum serum concentrations within 40 to 60 minutes after sublingual administration and is metabolized hepatically with a half-life of 2 to 3 hours.¹¹ Common adverse effects are nausea, vomiting, headache, dizziness, and syncope. Unlike the PDE-5 inhibitors, apomorphine is not associated with hypotension when used with antihypertensive, such as nitrates.

Priapism. Priapism is defined as prolonged involuntary erection unassociated with sexual stimulation. Subtypes of priapism are ischemic (characterized by low cavernosal blood flow), nonischemic (characterized by increased arterial flow), and stuttering (recurrent ischemic priapism).⁸⁷ It most commonly occurs during the third and fourth decades of life and is caused by inflow of blood to the penis in excess of outflow. The corpora cavernosa become firm and the corpus spongiosum flaccid. Intracavernosal pressures can exceed arterial systolic pressure, resulting in cell death. Priapism can occur from an imbalance in neural stimuli or interference with venous outflow or as a result of xenobiotic-induced inhibition of penile detumescence. α -Adrenergic antagonists prevent constriction of blood vessels supplying erectile tissue, resulting in priapism.¹²⁸ One in 10,000 patients taking trazodone develops priapism, which is thought to be related to its α -adrenergic antagonist effects.¹⁰⁵ Priapism can result from the injection of papaverine for the treatment of impotence.⁸⁷ Other xenobiotics associated with xenobiotic-induced priapism include prazosin, labetalol, guanethidine, hydralazine, phenothiazines, androgens, anticoagulants, ethanol, marijuana, and cantharidin^{62,128} (Table 21–3).

SSRI = selective serotonin reuptake inhibitor.

The goal in the treatment of priapism is detumescence with retention of potency. Initial therapy includes sedation with benzodiazepines, analgesia with opioids, ice packs, treatment of underlying systemic diseases such as sickle cell disease, and early urologic consultation. Aspiration with or without 9% NaCl solution irrigation of the corpora cavernosa may be effective. If priapism occurs secondary to α_1 -adrenergic antagonism, an α_1 -adrenergic agonist (100–500 $\mu\text{g/mL}$ phenylephrine solution) can be instilled into the corpora cavernosa at a dosage of 0.5 to 1 mL every 3 to 5 minutes up to 1 hour.⁸⁷ Oral terbutaline (5–10 mg) was effective for PGE₁-induced prolonged erections.^{75,103} For ischemic priapism symptoms greater than 4 hours, the American Urological Association guidelines do not recommend oral sympathomimetics.⁸⁷ Intracavernosal methylene blue has been used successfully as an alternative to intracavernosal sympathomimetics.⁸⁰ If the above measures fail, an operative venous shunt placement may be required.^{117,128}

FEMALE FERTILITY

The female reproductive system consists of the female gonadal organs and the respective hormonal system (Fig. 21–3). Fertility encompasses the reproductive system, the process of oocyte fertilization, and gestation. Female infertility may result from changes in hormone concentrations, direct toxicity to the ovum, interference with the transport of the ovum, or inhibition of implantation of the ovum in the uterus. Women usually notice reproductive abnormalities more quickly than men because menses may be affected, although infertility may occur while normal menses persists. Evaluation of female fertility is more difficult because of the complexity of the systems involved and the inaccessibility of the female germ cell, but it is feasible and involves investigations of the anatomy and hormonal concentrations. The following is a discussion of oogenesis, xenobiotics that disrupt oogenesis, and xenobiotics that affect early embryo gestation.

FIGURE 21–3. Schematic of female reproductive axis and sites of xenobiotic action. CNS = central nervous system; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; MAOI = monoamine oxidase inhibitor; SSRI = selective serotonin reuptake inhibitor.

Oogenesis

In contrast to men, women have a limited number of reproductive cells (ovarian follicles). Follicles are most numerous while a fetus is in utero, with the number decreasing to approximately 2 million at birth. By the time a woman reaches puberty, the majority of follicles have degenerated, leaving 300,000 to 400,000 ova, of which approximately 400 will eventually produce mature ova during a woman's reproductive years. In contrast, men produce millions of spermatozoa each day. The process of oogenesis requires secretion of GnRH from the hypothalamus, resulting in production of LH and FSH from the pituitary, which are required for ovarian follicle maturation.²⁴ FSH induces early maturation by stimulating granulosa and thecal cell proliferation and estrogen production. LH is required for ovulation and for the formation of the corpus luteum. The corpus luteum continues estrogen production and produces progesterone, which stimulates the uterus to develop an endometrium receptive to any fertilized ovum. Successful ovulation requires not only hormone secretion but also appropriate cyclic secretion.

Female Sexual Dysfunction

The National Health and Social Life Survey found that 43% of women in the United States (in comparison with 31% of men) reported having sexual dysfunction.⁶⁹ In 1999, a consensus panel of the American Foundation for Urologic Disease modified the four categories of female sexual dysfunction in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision to include the following: (1) sexual desire disorders, which include hypoactive sexual desire disorder and sexual aversion disorder; (2) sexual arousal disorder; (3) orgasmic disorder; and (4) sexual pain disorders, which include dyspareunia, vaginismus, and noncoital sexual pain disorder.^{2,15} The organic etiologies of female sexual dysfunction parallel those of male sexual and erectile dysfunction: vascular, neurologic, muscular, psychogenic, endocrinologic, and xenobiotic-induced causes.¹⁹ The medications implicated in female sexual dysfunction are similar to those mentioned earlier that decrease male fertility with antihypertensives; antidepressants, especially SSRIs; and antipsychotics as the most frequent causes.⁴⁵

Treatments for xenobiotic-induced female sexual dysfunction include decreasing medication dosages, switching to alternate medications with less adverse effects on sexual function such as bupropion and nefazodone, temporary cessation of the medication (drug holiday), or adding another medication to stimulate sexual function. Bupropion alone was as effective as fluoxetine for the treatment of depression but with less sexual dysfunction,³⁶ and when used in conjunction with SSRIs, bupropion improved sexual function compared with SSRIs alone.^{30,34} Sildenafil was successful for treating spinal cord–induced¹¹³ and antidepressant-induced sexual dysfunction,⁹⁴ but larger trials had mixed results with sildenafil for sexual arousal disorder.^{16,27} Sublingual apomorphine improved sexual function in women with hypoactive sexual disorder.²⁶

The majority of medical therapy for female sexual dysfunction is centered on hormonal manipulation, both estrogen and androgen supplementation. Estrogen replacement therapy is available in oral, dermal, vaginal ring, and topical cream formulations alone or in combination with progesterone.¹²¹ Estrogen therapy is associated with a higher incidence of coronary disease, breast cancer, stroke, and venous thromboembolism. Androgen therapy includes testosterone, which is available in oral, dermal, and topical preparations, and dehydroepiandrosterone.⁸ Adverse effects are weight gain, increased cholesterol concentrations, and androgenization.

Abortifacients. An abortifacient is defined as a xenobiotic that affects early embryonic gestation to induce abortion. Xenobiotics may act by flushing the zygote from the fallopian tube, blocking the uterine horn inhibiting implantation, inducing fetal resorption, or producing oxytocinlike activity that results in uterine irritation and contraction. Abortifacients may also indirectly affect pregnancy by altering hormonal concentrations through placental inhibition of human chorionic gonadotropin or progesterone production or through interference with progesterone receptors.

The toxic effects of abortifacients are varied. Many produce GI symptoms such as abdominal pain, nausea, and vomiting. Abdominal pain may be related to the oxytocic uterine effects associated with misoprostol and mifepristone, cytotoxic effects on the GI mucosa associated with methotrexate, leading to stomatitis and ulcers or hepatotoxicity associated with pennyroyal oil.³² Mifepristone inhibits implantation or has abortive effects that can cause severe vaginal bleeding. Other toxic effects are not necessarily related to their abortive mechanisms but due to the specific xenobiotic. Plant-derived abortifacients such as *Aristolochia* can cause nephrotoxicity, dong quai can cause photosensitivity, blue cohosh can cause seizure, and quinine can cause cardiac dysrhythmias.⁹² Congenital abnormalities of the scalp and skull defects, cranial nerve palsies, and limb defects such as talipes equinovarus are also reported with misoprostol use that did not terminate pregnancy³² (Table 21–4).

TABLE 21–4. Xenobiotics Used as Abortifacients

Source	Common Name	Xenobiotic	Mechanism/Toxicity
Inhibit Implantation			
<i>Abrus precatorius</i>	Leparchy pea	Abrin	Cytotoxic to albumin

"Selective progesterone receptor modulator"	—	Mifepristone, ulipristal	Nausea, vomiting, abdominal pain, vaginal bleeding
Abortive			
<i>Ranunculus</i> spp	Buttercup	Devil's claw	Similar to pennyroyal oil
<i>Angelica sinensis</i>	Dong quai	Furanocoumarin, phytoestrogen	Anticoagulant effects, gynecomastia, photodermatitis
<i>Daphne genkwa</i>	Lilac daphne	Yuanhuacine	
Lyso disinfectant	—		Death after intrauterine administration
<i>Mentha pulegium</i>	Pennyroyal	Pulegone	Hepatotoxicity
Methotrexate	—		Cytotoxic effects
Mifepristone	—		Nausea, vomiting, abdominal pain, vaginal bleeding
<i>Momordica charantia</i>	Bitter melon	α -Momocharin	Similar to trichosanthin
<i>Moringa oleifera</i>	Horseradish tree	<i>Moringa oleifera</i>	100% abortifacient in rats
<i>Podophyllum peltatum</i>	Mayapple	Podophyllin	Podophyllin toxicity
<i>Trichosanthes kirilowii</i>	Snake gourd	Trichosanthin (compound Q)	Inhibits protein synthesis, ↓ HCG, ↓ progesterone
Cytotoxic			
<i>Aristolochia</i> spp	Birthwort	Aristolochic acid	Nephrotoxicity
<i>Caulophyllum thalictroides</i>	Blue cohosh	Methylcytosine	Nicotinic activity
<i>Cimicifuga racemosa</i>	Black cohosh	unknown	Nausea, vomiting, headache, rare hepatotoxicity
<i>Cinchona</i> spp	Quinine bark	Quinine	Cinchonism
<i>Ergot</i>	Ergot	Ergotamines	Vasospasm
<i>Lagenaria breviflora</i> Robert	Wild colocynth	<i>Lagenaria breviflora</i> Robert	Antiimplantation, oxytocic
Misoprostol		Prostaglandin E ₂ analogue	Marketed as Cytotec for gastric ulcers and Arthrotec

HCG = human chorionic gonadotropin

In a US poison center study, five of 43 pregnant women who intentionally overdosed used known abortifacients, including quinine, misoprostol, methylergonovine, and oral contraceptives. Four of these patients developed vaginal bleeding and cramping, but no short-term (1–3 days) fetal demise was reported.¹⁰¹ The use of abortifacients is more common in underdeveloped countries and in people without access to safer methods for termination or prevention of pregnancy.

Toxicity of Aphrodisiacs

Aphrodisiacs heighten sexual desire, pleasure, or performance and include xenobiotics from the plant, animal, and mineral kingdoms.³⁸ The search for an effective aphrodisiac has continued for thousands of years. Ancient fertility cults used

Datura, belladonna, and henbane as aphrodisiacs. Yohimbine has been used by African cultures to enhance sexual prowess, and mandrake was used in medieval Europe. A small sampling of other xenobiotics recommended as aphrodisiacs include oysters, live beetles, vitamin E, ginseng, saffron, horny goat weed, and tongkat ali. Because there are few measurable objective parameters, research in this area is lacking. Most published studies evaluating aphrodisiacs have been conducted in animals, and little information is available in humans. Toxicity can result from the aphrodisiac or adulterants¹³ (Table 21–5).

TABLE 21–5. Xenobiotics Used as Aphrodisiacs

<i>Xenobiotic</i>	<i>Toxicity</i>
<i>Oral</i>	
Cantharidin	Vesicant actions—GI mucositis and hemorrhage, hematuria
Cathinone (hagigat)	Hypertension, tachycardia
Dapsone	Methemoglobinemia, hemolysis
Ginseng	Ginseng abuse syndrome, vaginal bleeding
Lead	Anemia, abdominal pain
<i>Mandragora officinarum</i> (mandrake)	Anticholinergic
<i>Myristica fragrans</i> (nutmeg)	Hallucinogen, GI upset
<i>Tribulus terrestris</i> (Puncturevine)	Gynecomastia
Yohimbine	Paresthesias, hypertension
<i>Topical</i>	
Cantharidin	Vesicant actions—GI mucositis and hemorrhage, hematuria
Bufotoxin	Cardioactive steroid
<i>Inhalation</i>	
Alkyl nitrites (amyl, butyl, isobutyl nitrites)	Hemolytic anemia, methemoglobinemia, orthostasis

Dopamine, NO, oxytocin, and ACTH facilitate sexual behavior. Dopamine stimulates the forebrain and midbrain and leads to an increase in sexual response and arousal. In animals, dopamine agonists, such as apomorphine and quinpirole, have proerectile effects through stimulation of dopamine pathways, increasing NO in the paraventricular nucleus in the hypothalamus, and releasing oxytocin.⁹⁰ Other preparations tested for the treatment of impotence include bromocriptine,^{1,22} nitroglycerin,⁹¹ zinc,¹⁰ oxytocin,⁷² and LH.⁷¹ Endogenous opioids, GABA, and norepinephrine are associated with decreased sexual behavior. Serotonin is generally inhibitory to sexual function, but the effects are dependent on the receptor subclass. Whereas 5-HT_{1A} receptor stimulation inhibits erection but facilitates ejaculation in rats, 5-HT_{2C} receptors facilitate male sexual behavior.⁹⁰ Various serotonergic drugs, including trazodone, nefazodone, bupropion, and clomipramine, are reported to improve sexual dysfunction.^{105,127}

URINARY SYSTEM

The urinary system is composed of the kidneys, ureters, bladder, and urethra (Chap. 28). Many xenobiotics are concentrated by the kidneys and eliminated in the urine. The following discusses the effect of xenobiotics on the bladder and urine.

Bladder Anatomy and Physiology. The bladder is a hollow, muscular reservoir composed of two parts—the body and the neck—and normally stores up to 350 to 450 mL of urine in adults. A smooth muscle, the detrusor muscle, makes up the bulk of the body and contracts during urination. Urine from the ureters enters the bladder at the uppermost part of the trigone, an area in the posterior wall of the bladder, and leaves via the neck and the posterior urethra. Surrounding the neck and posterior urethra is smooth muscle interlaced with elastic tissue to form the internal sphincter. Sympathetic innervation from the lumbar spinal cord to the internal sphincter maintains smooth muscle contraction. Distal to the internal sphincter is an area with voluntary skeletal muscle that forms the external sphincter and is innervated by somatic pudendal nerves.

The nerve supply and neurophysiology of urination involve interplay among lumbar sympathetic nerves, sacral parasympathetic nerves, and sacral somatic nerves. Figure 21–4 illustrates the physiology of micturition. With bladder filling, norepinephrine is released by sympathetic postganglionic fibers. α -Adrenergic receptors predominate in the internal sphincter and the bladder neck, and β -adrenergic receptors supply the detrusor wall of the bladder. Stimulation of α -

adrenergic receptors results in internal sphincter contraction and increased bladder outlet resistance, and stimulation of β -adrenergic receptors leads to detrusor relaxation and bladder filling.¹¹⁹ In micturition, parasympathetic pre- and postganglionic fibers release acetylcholine to M_2 and M_3 muscarinic receptors in the detrusor muscle. Stimulation of M_3 receptors is responsible for detrusor muscle contraction and bladder emptying.³⁰ Conversely, anticholinergics prevent bladder emptying and result in urinary retention.^{28,29,33,48,53,88}

FIGURE 21–4. Schematic description of the physiology of micturition. (The dotted lines show the efferent pathway.)

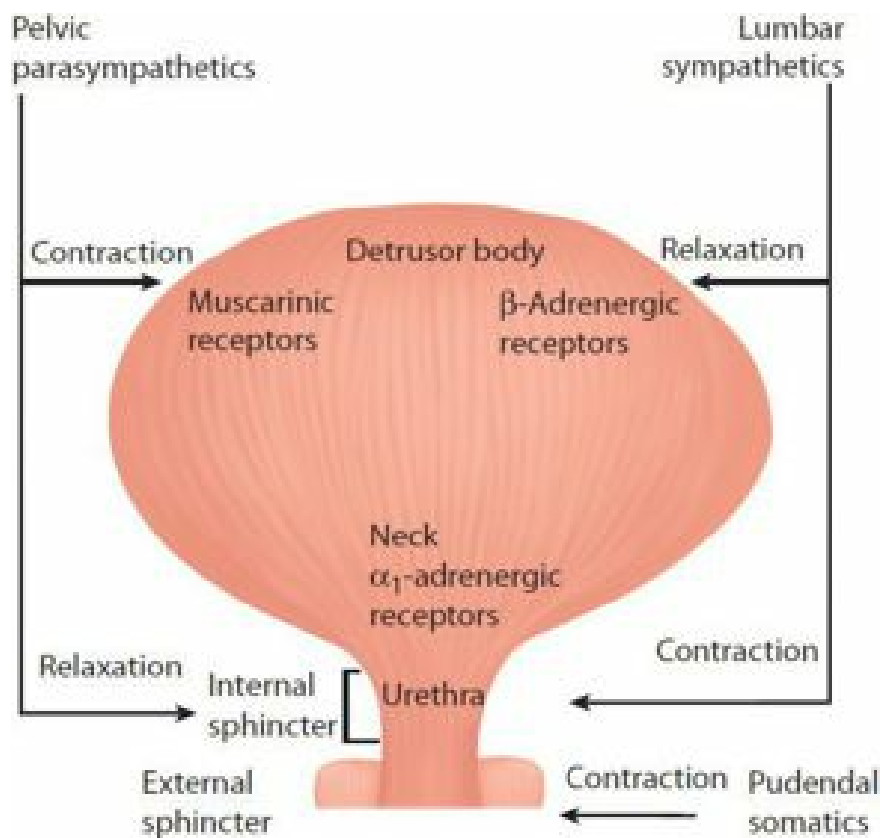

Urinary Abnormalities. Urinary incontinence is common in elderly adults. As age increases, bladder size decreases, resulting in more frequent emptying. Early detrusor contraction, even with low bladder volumes, occurs more commonly in elderly adults, causing a sense of urgency. There are many etiologies for urinary incontinence, including various xenobiotic exposures (Fig. 21–5). General or regional anesthesia, bladder instrumentation, and medications may produce bladder atony, leading to incontinence.³³ Functional incontinence can also result from use of any medication that causes impaired cognition or decreased mobility as recognized with the use of sedative–hypnotics and opioids.³³ Xenobiotics used in the treatment of urinary incontinence include the anticholinergics darifenacin, fesoterodine oxybutynin, solifenacin, tolterodine, trospium chloride, imipramine, botulinum toxin A, and venlafaxine. Venlafaxine is a serotonin and norepinephrine reuptake inhibitor that acts centrally at the sacral cord pudendal motor nucleus to stimulate urethral rhabdosphincter contraction.⁴² Urinary retention can be obstructive, neurogenic, psychogenic, or pharmacologic in origin. Medications associated with urinary retention include sympathomimetics, anticholinergics, antidysrhythmics (quinidine, procainamide, disopyramide), antidepressants, antipsychotics, hormonal agents (progesterone, estrogen, testosterone), and muscle relaxants.^{33,48} In men older than 50 years, benign prostatic hyperplasia is the most common cause of bladder outlet obstruction, leading to

decreased urinary output and urinary retention. Treatment of benign prostatic hyperplasia consists of 5 α -reductase inhibitors and α -adrenergic antagonists. 5 α -Reductase inhibitors (finasteride, dutasteride) block the conversion of testosterone to dihydrotestosterone to decrease prostate volume.⁸³ α_1 -Adrenergic antagonists (doxazosin, terazosin, alfuzosin, tamsulosin) decrease urethral α -adrenergic contraction.⁵⁰ Table 21–6 lists xenobiotics associated with urinary retention and incontinence.

TABLE 21–6. Xenobiotics That Cause Urinary Retention and Incontinence

<i>Retention</i>	<i>Incontinence</i>
α_1 -Adrenergic agonists	α_1 -Adrenergic antagonists
Amantadine	Antipsychotics
Antihistamines	Clozapine
Anticholinergics	Chlorpromazine
Atropine	Haloperidol
Dicyclomine	Thioridazine
Glycopyrrolate	Cholinesterase inhibitors
Hyoscyamine	Estrogen hormone replacement therapy
Ipratropium	Diuretics
Oxybutynin	Naloxone (for opioid-induced retention)
Tiotropium	SSRIs
Tolterodine	
Antipsychotics	
Aripiprazole	
Olanzapine	
Phenothiazines	
Risperidone	
Quetiapine	
Ziprasidone	
Atomoxetine	
Baclofen (intrathecal)	
Benzodiazepines	
Botulinum toxin	
Calcium channel blockers	
Carbamazepine	
Cyclic antidepressants	
Cyclopentolate	
Dantrolene	
Disopyramide	
Flecainide	
Imiquimod	
Kava	
MDMA	
Mirtazapine	
NSAIDs	
Opioids	
SSRIs	
Citalopram	
Duloxetine	
Escitalopram	
Fluoxetine	
Fluvoxamine	
Milnacipran	
Reboxetine	
Theophylline	

NSAID = nonsteroidal antiinflammatory drug; SSRI = selective serotonin reuptake inhibitor.

External sphincter (contraction)

Duloxetine
Reboxetine

Detrusor (contraction)

Bethanechol
Cholinesterase inhibitors
Carbamates
Donepezil
Galantamine
Organic phosphorus compounds
Rivastigmine

Internal sphincter (contraction)

α_1 -Adrenergic agonists
Ephedrine
Midodrine
Pseudoephedrine
Methamphetamine
MDMA

Internal sphincter (relaxation)

α -Adrenergic antagonists
Doxazosin
Phentolamine
Prazosin
Terazosin
Antipsychotics
Clozapine
Thioridazine

Detrusor (relaxation)

Anticholinergics
Amantadine
Antihistamines
Astemizole
Atropine
Cyclic antidepressants
Cyclopentolate
Dicyclomine
Hyoscyamine
Ipratropium
Dicyclomine
Oxybutynin
Propantheline
Tolteridine
Antipsychotics
Clozapine
Phenothiazines
Risperidone
Ziprasidone
 α_1 -Adrenergic antagonists
Botulinum toxin
Calcium channel blocker
Flunarizine
Type I antidysrhythmics
Cyclic antidepressants
Disopyramide
Flecainide

FIGURE 21–5. Graphic of the bladder and sites of xenobiotic effects. MDMA = 3,4-methylenedioxy-N-methylamphetamine.

Abnormalities in Urinalysis. Abnormalities of the urinalysis are often useful in identifying xenobiotic exposures. Crystalluria is a common finding and may be normal, but the presence of crystals may aid in diagnosis. Crystal formation is dependent on supersaturation of the urine and changes in the urine temperature or pH. The most common crystals are calcium oxalate, uric acid, and phosphate. However, crystals of various xenobiotics alone or in combination with other crystals may be seen in ingestions.⁴⁶ The urinalysis in patients who ingest ethylene glycol may reveal calcium oxalate or hippurate crystals in 50% of cases. Calcium oxalate crystals are monohydrates (prism or needlelike) or dihydrates (envelope shaped). Hippurate crystals are needle shaped.⁹⁷ Birefringent single or conglomerates of hexagonal crystals are noted after massive primidone poisoning and result from precipitation of primidone in the urine.¹¹⁸ Crystalluria may be present with therapeutic doses of salicylate, phenacetin, sulfonamide, and quinolones. Oral sodium phosphate preparations for bowel cleansing have caused calcium phosphate calcifications leading to acute phosphate nephropathy.⁷⁸ After large exposures, crystals can be seen with methotrexate, amoxicillin, cephalexin, ampicillin, and indinavir (Table 21–7).

TABLE 21–7. Xenobiotics That Cause Crystalluria

Antivirals
Acyclovir

Orlistat
Nitrofurantoin
Primidone
Protease inhibitors
Atazanavir
Indinavir
Quinolones
Salicylates
Sodium phosphate

Sulfonamides

Sulfadiazine

Sulfamethoxazole

Thiabendazole

Triamterene

Xylitol

Urine color is dependent on several factors, including pH, concentration, natural pigments, and length of time exposed to air. Normal urine specimens should be clear and yellow in coloration. Whereas dilute urine secondary to diuretic use, diabetes mellitus, diabetes insipidus, or simply hydration can appear colorless, concentrated urine is usually orange. Fluorescein, found in some antifreeze products, can be detected by illumination of the urine with a Wood lamp, although this diagnostic test has poor sensitivity and specificity.¹²⁰ One study used urine samples from a group of unpoisoned children and three urine samples with added sodium fluorescein to examine physicians’ ability to detect urinary fluorescence with a Wood lamp against a fluorometer. The fluorometer reported fluorescence in 100% of the urine samples, but the physicians reported fluorescence in 70% to 80% of the samples.⁹⁸ Urinary fluorescence, even when present, is not useful as a diagnostic test. [Table 21–8](#) lists other causes of colored urine.

Triamterene

There are multiple causes of hematuria⁷⁹ (Table 21–9). It can occur with xenobiotic-induced interstitial nephritis, a condition distinguished by fever, rash, eosinophilia, eosinophiluria, azotemia, and oliguria.⁴⁰ Hemorrhagic cystitis is a more frequent cause of hematuria and is associated with a number of xenobiotics. The clinical presentation of hemorrhagic cystitis includes hematuria, dysuria, and urinary frequency. Criteria for diagnosis of hemorrhagic cystitis¹⁰ include a history of gross hematuria, laboratory findings, of microscopic hematuria (>3 red blood cells/high-power field), platelet count above 50,000/mm³, and a negative urine culture result.¹⁰⁴ When in doubt, the diagnosis may be confirmed by cystoscopy, which reveals an inflamed, hyperemic, and sometimes ulcerated bladder mucosa.

Toluene

Xylene

Statins

Atorvastatin

Rosuvastatin

BCG = Bacillus Calmette-Guerin; COX = cyclooxygenase; NSAID = nonsteroidal antiinflammatory drug.

Cyclophosphamide-related hemorrhagic cystitis was first described in 1959⁸⁶ and is the best-documented type of xenobiotic-induced hemorrhagic cystitis.⁵¹ As many as 46% of patients receiving cyclophosphamide develop hemorrhagic cystitis.^{43,61,67,70} Acrolein, the causative xenobiotic, is a metabolite of cyclophosphamide that damages the urothelium when excreted (Chap. 52).^{101,115} Cyclophosphamide- and ifosfamide-induced hemorrhagic cystitis may be prevented with mesna therapy.⁴

An outbreak of hemorrhagic cystitis occurred in workers in a packaging plant after exposure to chlordimeform, a formamidine insecticide used to control mites and insects on cotton. Nine workers developed abdominal pain, dysuria, urgency, and hematuria, with biopsy-proven hemorrhagic cystitis.⁴⁷ Eight young adults developed painful hematuria after consuming “bootleg” methaqualone. The cause was orthotoluidine, a compound used in the synthesis of methaqualone, and the symptoms occurred within 6 hours of ingestion.⁵⁴ Chronic ketamine and methoxetamine abuse is associated with the development of hemorrhagic ulcerative cystitis.¹¹¹ Rare cases of hemorrhagic cystitis have also been described with ticarcillin,⁸¹ nafcillin, penicillin G, carbenicillin, piperacillin, isoniazid, indomethacin, tiaprofenic acid, and busulphan.^{52,85,112}

Treatment for other causes of hemorrhagic cystitis includes bladder irrigation with saline, alum, PGs, silver nitrate, formalin, and phenol. Systemic therapy include estrogens, vasopressin, aminocaproic acid, and hyperbaric oxygen.¹²⁴ These therapies may have inherent adverse effects as well. Aluminum toxicity has been reported with alum bladder irrigation for hemorrhagic cystitis in patients with kidney failure.¹⁰⁰

SUMMARY

- Xenobiotics decrease fertility and fecundity by decreasing FSH and LH centrally or altering sperm production in men and altering ovarian function in women.
- Xenobiotics can cause sexual dysfunction by decreasing libido in men and women, increasing prolactin, decreasing dopamine, or causing erectile dysfunction in men.

- Therapies for male erectile dysfunction can lead to priapism.
- Abortifacients usually prevent embryo implantation or induce uterine contractions leading to increased vaginal bleeding and abdominal pain.
- Xenobiotics can alter bladder function to cause urinary retention or incontinence as well as changing the characteristics of urine in terms of color, hematuria, or crystal formation.

22 HEMATOLOGIC PRINCIPLES

Marco L.A. Sivilotti

Blood is rightfully considered the vital fluid, because every organ system depends on the normal function of blood. Blood delivers oxygen and other essential substances throughout the body, removes waste products of metabolism, transports hormones from their origin to site of action, signals and defends against threatened infection, promotes healing via the inflammatory response, and maintains the vascular integrity of the circulatory system. It also serves as the central compartment in classical pharmacokinetics and thereby comes into direct contact with virtually every systemic xenobiotic that acts on the organism.⁸⁹ The ease and frequency with which blood is assayed, its central role in functions vital to the organism, and the ability to analyze its characteristics, at first by light microscopy and more recently with molecular techniques, have enabled a detailed understanding of blood that has advanced the frontier of molecular medicine.

In addition to transporting xenobiotics throughout the body, blood and the blood-forming organs can at times be directly affected by these same xenobiotics. For example, decreased blood cell production, increased blood cell destruction, alteration of hemoglobin, and impairment of coagulation can all result from exposure to many xenobiotics. The response in many cases depends on the nature and quantity of the xenobiotic as well as the capacity of the system to respond to the insult. In other cases, no clear and predictable dose–response relationship can be determined, especially when the interaction involves the immune system. These latter reactions are often termed idiosyncratic, reflecting an incomplete understanding of their causative mechanism. In general, such reactions can often be reclassified when advancing knowledge identifies the characteristics that render the individual vulnerable.

HEMATOPOIESIS

Hematopoiesis is the development of the cellular elements of blood. The majority of the cells of the blood system may be classified as either lymphoid (B, T, and natural killer lymphocytes) or myeloid (erythrocytes, megakaryocytes, granulocytes, and monocytes). All of these cells originate from a small common pool of totipotent cells called hematopoietic stem cells. Indeed, the study of this process and its regulation has provided fundamental insight into embryogenesis, stem cell pluripotency, and complex cell-to-cell signaling and interaction.

Bone Marrow

Marrow spaces within bone begin to form in humans at about the fifth fetal month and become the sole site of granulocyte and megakaryocyte proliferation. Erythropoiesis moves from the liver to the marrow by the end of the last trimester. At birth, all marrow contributes to blood cell formation and is red, containing very few fat cells. By adulthood, the same volume of hematopoietic marrow is normally restricted to the sternum, ribs, pelvis, upper sacrum, proximal femora and humeri, skull, vertebrae, clavicles and scapulae. Extramedullary hematopoiesis in the liver and spleen may reemerge as a compensatory mechanism under severe stimulation.

Progenitor cells must interact with a supportive microenvironment to sustain hematopoiesis. The hematopoietic stroma consists of macrophages, fibroblasts, adipocytes, and endothelial cells. The extracellular matrix is produced by the stromal cells and is composed of various fibrous proteins, glycoproteins, and proteoglycans, such as collagen, fibronectin, laminin, hemonectin, and thrombospondin. Hematopoietic progenitor cells have receptors to particular matrix molecules. The extracellular matrix provides a structural network to which the progenitors are anchored. As the cells approach maturity, they lose their surface receptors, allowing them to leave the hematopoietic space and enter the venous sinuses. Blood cell release depends upon the development of a pressure gradient that drives mature cells through channels in endothelial cell cytoplasm. This pressure is increased by erythropoietin and by granulocyte colony-stimulating factor.

Stem Cells

A stem cell is capable of self-renewal, as well as differentiation into a specific cell type. The pluripotent hematopoietic stem cells can therefore continuously replicate while awaiting the appropriate signal to differentiate into either a myeloid or a lymphoid stem cell (Fig. 22–1). Stem cells represent only 1 in 100,000 of the nucleated cells of the bone marrow, and most of these stem cells are usually quiescent. Nevertheless, these relatively few cells are directly responsible for the estimated 3 billion red cells, 2.5 billion platelets, and 1.5 billion leukocytes per kilogram of body weight produced each

day. In response to hemolysis or infection, substantially larger numbers of blood cells can be produced.⁷⁰ Multiple steps are involved in the commitment of less-differentiated cells to more mature cell lines. The final steps in the maturation of erythrocytes alone, for example, involve extensive remodeling, the restructuring of cellular membranes, the accumulation of hemoglobin, and the loss of nuclei and organelles.

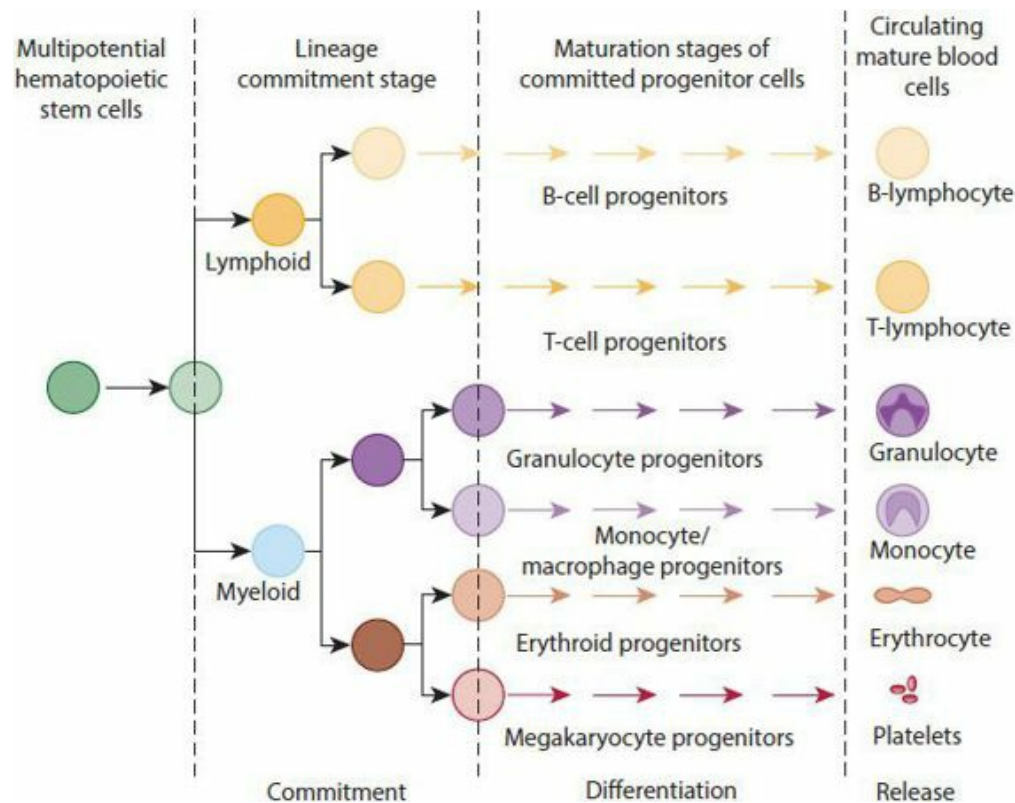

FIGURE 22–1. Principles of hematopoiesis. Commitment refers to the apparent inability of progenitor cells to generate hematopoietic stem cells. Following differentiation, the various mature blood cells are released into the circulation.

Multipotent mesenchymal stem cells capable of differentiating into other tissue lines, including hepatic, renal, muscle and perhaps neuronal, are also found in the bone marrow.⁴⁰ Furthermore, tissue-specific stem cells capable of self-renewal are believed to reside in numerous other organs and to play a fundamental role in repair and regeneration.²¹ A variety of strategies have likely evolved to protect the stem cell from injury due to xenobiotics and radiation, and a better understanding of these effects promises to improve our understanding of toxicity and treatment. The hematopoietic stem cell has provided fundamental insights into regenerative biology, and it remains a focus of intense research given the profound implications for organ homeostasis, tissue repair, and gene therapy.^{58,59}

Cytokines

Cytokines are soluble mediators secreted by cells for cell-to-cell communication. Initially termed growth factors, it is now recognized that not all cytokines are growth factors. Cytokines promote or inhibit the differentiation, proliferation, and trafficking of blood cells and their precursors. Importantly, they can also inhibit apoptosis, and their absence therefore results in the self-destruction of unwanted cells. They include growth factors or colony-stimulating factors (CSFs), interleukins, monokines, interferons, and chemokines. At baseline, these act in concert to maintain normal blood counts. In response to antigens or other stimuli, cytokines are released to combat perceived infection. Recombinant cytokines are being developed for therapeutic use in immunocompromised patients, transplant recipients, and those with sepsis and cancer. They have also been used in clinical toxicology for the treatment of colchicine and podophyllum toxicity.^{29,43}

The growth factors are glycoproteins necessary for the differentiation and maturation of individual or multiple cell lines. They fall into two families based on their target receptors. The ligands of the cytokine receptor family include growth hormone, interleukin-2 (IL-2), macrophage colony-stimulating factor-1 (CSF-1), granulocyte-macrophage colony-stimulating factor (GM-CSF), γ -interferon, and granulocyte colony-stimulating factor (G-CSF), to name a few. The second group, the tyrosine kinase family, includes Kit ligand and insulinlike growth factor-1 receptor (IGF-1R), a member of the insulin family.

Cell Surface Antigens

Using monoclonal antibody technology, cell surface antigens are used to characterize cell types. The cluster designation (CD) nomenclature was introduced by immunologists to ensure a common language when confronted with multiple

antibodies to the same leukocyte cell-surface molecule, and hundreds of such unique molecules have been classified.¹⁰⁷ For example, the CD34 antigen is a 115-kilodalton (kDa) highly glycosylated transmembrane protein that is selectively expressed by primitive multipotent hematopoietic stem cells shortly after activation, but is absent from mature T and B lymphocytes.⁶¹ Advances in genomics and proteomics now complement the immunologic designation, but the ability to subtype blood cells phenotypically has transformed the approach to the leukemias, autoimmune disease, transplantation medicine, and thromboembolic disease.

The human leukocyte antigen (HLA) system denotes the major histocompatibility complex in humans, a group of genes involved in antigen presentation to T-lymphocytes, the complement system, cancer surveillance, and autoimmune disease. The rich variation in HLA genes, with more than 100 known alleles at six loci, is believed to be the result of selective pressure to deter individuals with similar HLA from mating. Such sexual selection enhancing diversity would protect a population from coevolving pathogens that attempted to mimic a specific human epitope and avoid immune attack. Indeed, humans appear to be able to distinguish and preferentially choose partners with HLA alleles different from their own using smell, promoting heterozygous diversity.⁶⁵ Exposure to blood transfusions, pregnancy, and organ grafts can generate antibodies against nonself HLAs.

Aplastic Anemia

Aplastic anemia is characterized by pancytopenia on peripheral smear, a hypocellular marrow, and delayed plasma iron clearance. Severe aplastic anemia denotes a granulocyte count of less than 500 cells/mm³, a platelet count of less than 20,000/mm³, and a reticulocyte count of less than 1% after correction for anemia. Following acute insult and depletion of extracirculatory reserves, cell line counts fall at a rate inversely proportional to their life span: granulocytes (half-life 6–12 hours in the circulation) disappear within days, platelets (life span of 7–10 days) decline by half in about one week, while erythrocytes (normal life span 120 days) decline over weeks in the absence of bleeding or hemolysis. Approximately 1000 new cases of aplastic anemia are diagnosed yearly in the United States. The incidence is two to three times higher in Asia, perhaps because of a combination of genetic, environmental, and infectious factors.¹⁰⁵ Aplastic anemia may be inborn (as in Fanconi anemia) or acquired. A variety of xenobiotics such as benzene, pesticides, and chloramphenicol are associated with acquired aplastic anemia (Table 22–1),^{20,106} but causality is uncertain given uncertain case ascertainment and other biases. More recent epidemiologic studies demonstrate that specific causes are identified in relatively few cases.⁵¹

TABLE 22–1. Xenobiotics Associated with Aplastic Anemia

Analgesics
Acetaminophen (APAP)
Diclofenac
Dipyrone
Indomethacin
Phenylbutazone
Salicylates

Occupational

Arsenic^a

Benzene^a

Cadmium

Copper

Pesticides

Radiation^a

^aDenotes xenobiotics that predictably result in bone marrow aplasia following a sufficiently large exposure.

Generally speaking, the majority of cases of so-called idiosyncratic aplastic anemia are caused by autoimmune attack on CD34⁺ hematopoietic stem cells. Following an exposure to an inciting antigen, cytotoxic T-cells secrete interferon- γ and tumor necrosis factor α , which destroy progenitor cells, eventually depleting mature leukocytes, erythrocytes, and platelets in circulation.¹⁰⁶ As with other autoimmune diseases, certain HLA patterns are associated with a genetic predisposition for the condition, namely the HLA DR2. Clozapine-induced agranulocytosis is associated with the HLA B38, DR4, and DQ3 haplotypes.⁷¹ Immunosuppressive therapy or allogeneic stem cell transplantation allows recovery of hematopoiesis, and survival is now expected.¹⁰⁵

It is important to distinguish immunologic xenobiotic-induced aplastic anemia from the direct myelotoxic effects of radiation and chemotherapy. Following exposure to ionizing radiation, a pancytopenia ensues due to injury to stem and progenitor cells. While atom bomb survivors rarely developed aplastic anemia,⁴⁸ fractionated whole body radiation of at least 10 Gy is used to intentionally destroy bone marrow stem cells prior to hematopoietic stem cell transplantation. Cancer chemotherapy is often dosed to the end point of reversible hematopoietic toxicity. Vacuolated pronormoblasts can be found in the bone marrow when aplasia is due to a myelotoxic drug, and treatment consists primarily of stopping the offending xenobiotic while supporting cell lines and preventing infection and bleeding. Other nonimmunologic mechanisms of aplasia are identified in specific cases. For example, the severe pancytopenia that occasionally occurs following 5-fluorouracil therapy is caused by a deficiency of dihydropyrimidine dehydrogenase present in 3% to 5% of whites.¹⁰¹

THE ERYTHRON

The erythron can be considered to be a single yet dispersed tissue, defined as the entire mass of erythroid cells from the first committed progenitor cell to the mature circulating erythrocyte. This functional definition emphasizes the integrated regulation of the erythron, both in health and disease. The primary function of the erythron is to transport molecular oxygen throughout the organism. To accomplish this, adequate numbers of circulating erythrocytes (nearly half of the blood by volume) must be maintained. These erythrocytes must be able to preserve their structure and flexibility to circuit repeatedly through the microcirculation and to resist oxidant stress accumulated during their life span.⁸¹ The erythrocyte also plays a key role in modulating vascular tone. Interactions between oxyhemoglobin and nitric oxide help match vasomotor tone to local tissue oxygen demands.^{30,38,42,64,88}

Homeostasis of erythron proliferation is primarily maintained by the equilibrium between stimulation via the hormone erythropoietin and apoptosis controlled by two receptors, Fas and FasL, expressed on the membranes of erythroid precursors. At the other extreme, erythrocytes are culled from the circulation at the end of their life span primarily by the action of the spleen. With age, erythrocytes become less able to negotiate the narrow red pulp passages in the spleen and are phagocytosed by macrophages. By filtering out these senescent cells, the spleen minimizes entrapment in the microvasculature of other organs and prevents spillage of intracellular contents including hemoglobin into the intravascular circulation.

Erythropoietin

Erythropoietin (EPO) is a glycoprotein hormone of molecular weight 34,000 Da that is produced in the epithelial cells lining the peritubular capillaries of the kidney. Anemia and hypoxemia stimulate its synthesis. EPO receptors are found in human erythroid cells, megakaryocytes, and fetal liver. EPO promotes erythroid differentiation, the mobilization of marrow progenitor cells, and the premature release of marrow reticulocytes. The cell most sensitive to EPO is a cell between the erythroid colony-forming unit (CFU-E) and the proerythroblast. The absence of EPO results in DNA cleavage and erythroid cell death.

The Mature Erythrocyte

The mature erythrocyte (red blood cell) is a highly specialized cell, designed primarily for oxygen transport. Accordingly, it is densely packed with hemoglobin, which constitutes approximately 90% of the dry weight of the erythrocyte. During maturation, the erythrocyte loses its nucleus, mitochondria, and other organelles, rendering it incapable of synthesizing new protein, replicating, or using the oxygen being transported for oxidative phosphorylation. Its metabolic repertoire is severely limited and largely restricted to a few pathways (described below under Metabolism). In general, the enzymatic pathways are those required for optimizing oxygen and carbon dioxide exchange, transiting the microcirculation while maintaining cellular integrity and flexibility, and resisting oxidant stress on the iron and protein of the cell. The characteristic biconcave discocyte shape is dynamically maintained, increasing membrane surface-to-cell volume. This shape decreases intracellular diffusion distances to the cell membrane and allows plastic deformation when squeezing

through the microcirculation. The shape is the net sum of elastic and electrostatic forces within the membrane, surface tension, and osmotic and hydrostatic pressures. The cell membrane contains globular proteins floating within the phospholipid bilayer. The major blood group antigens are carried on membrane ceramide glycolipids and proteins, particularly glycophorin A and the Rh proteins. Membrane proteins generally serve to maintain the structure of the cell, to transport ions and other substances across the membrane, or to catalyze a limited number of specific chemical reactions for the cell.

Structural Proteins. The cell membrane is coupled to, and interacts dynamically with, the cytoskeleton, allowing changes in cell shape such as tank treading or rotation of the membrane relative to the cytoplasm. This cytoskeleton consists of a hexagonal lattice of proteins, especially spectrin, actin, and protein 4.1, which interact with ankyrin and band 3 in the membrane to provide a strong but flexible structure to the membrane. Other essential structural proteins include tropomyosin, tropomodulin, and adducin. Absence or abnormalities of these proteins can result in abnormal erythrocyte shapes such as spherocytes and elliptocytes.

Transport Proteins. Many specialized transport proteins are embedded in the erythrocyte membrane. These include anion and cation transporters, glucose and urea transporters, and water channels. The erythrocyte membrane is relatively impermeable to ion flux. Band 3 anion-exchange protein plays an important role in the chloride-bicarbonate exchanges that occur as the erythrocyte moves between the lung and tissues. Glucose, the sole source of energy of the erythrocyte, crosses the membrane by facilitated diffusion mediated by a transmembrane glucose transporter. Sodium-potassium adenosine triphosphatase ($\text{Na}^+\text{-K}^+\text{-ATPase}$) maintains the primary cation gradient by pumping sodium out of the erythrocyte in exchange for potassium.
